High-performance liquid chromatography (HPLC) is one of several separation techniques that are based on the differential migration of an analyte (solute) through a fixed medium as the result of a driving force, the eluent. In the case of HPLC, the eluent is typically either a binary or ternary mixture of solvents and the stationary phase is most often a porous adsorbent or a chemically bonded phase attached to a porous substrate. The rate of migration of an individual solute and the separation between groups of solutes are governed by their interactions with the stationary phase. Thus, the optimization of an HPLC method involves the selection/adjustment of the physical and chemical parameters which control the rate of migration of the solute in such a fashion that baseline resolution is obtained between it and other co-analytes or interfering compounds within the mixture. In doing this, given a series of closely related compounds, it is important to identify structural differences between solutes and to maximize the interactions with the stationary phase arising from them. This article considers the important physical and chemical aspects of the solute, eluent, and stationary phase in terms of chemical equilibria, solute structure, eluent conditions, operational parameters, and nonideal effects. Likewise, as several approaches may lead to acceptable analytical separations, other performance criteria such as simplicity, reliability, speed, and cost also are discussed in terms of arriving at the optimal method.

1 INTRODUCTION

Since the late 1960s HPLC-based methods have become increasingly popular in the analysis of pharmaceuticals and currently are the most widely used procedures.[1–3] Their growing acceptance has resulted from the inherent versatility and reliability of the methodology, as well as from improvements in hardware performance and ease of automation of the procedures. Likewise, fundamental sample considerations such as thermal instability, low volatility, and matrix complexity have been important contributing factors in their increasing use.

1.1 Understanding the Problem or Sample

In developing appropriate cost-effective HPLC methods, as with analytical procedures in general, it is important to consider the total problem to be solved. This not only includes the development and optimization of a method in terms of analyte and matrix considerations, separation and detection design, and validation, but it also should take into account the end-usage and user skills. Often, these latter aspects may be the overriding factors in determining the final assay design. If the intended application of a new procedure is as a routine high-throughput assay for assuring that a single active ingredient is within acceptable levels during manufacture of the formulated product, then simplicity, reliability, speed, and cost become important factors in selecting the overall methodology.

What is eloquent in the research and development laboratory may be too complex, expensive, and unreliable for the quality assurance setting. Often simple isocratic approaches are more effective than gradient elution procedures and methods that are based on them are easier to carry out by the less trained practitioner. Similarly, ease of use and reliability are two important considerations in choosing a given approach such as the use of reversed phase (RP) conditions over normal phase

(NP) conditions, even though in many cases the latter may be more selective in resolving a series of closely related polar solutes or structural isomers. In cases where compounds are easily separated, there may be distinct advantages in more effective utilization of hardware and decreased costs in supplies and labor by using less retentive and shorter columns operated at higher flow rates. Although rapid analysis (RA) is a concept that emerged two decades ago[4] and has been applied to many types of pharmaceutical separations, it works best for assays involving single components or simple combination products because they do not require the higher resolving power of longer columns. In many of these types of procedures only 1000–2000 plates may be needed to produce an effective separation.[5] Columns for RA, which are available from a number of manufactures, are typically 30–50 mm in length and are packed with 2–5 μm porous materials. However, columns packed with nonporous particles have been developed recently as alternative media for carrying out highly efficient fast separations.[6] Rapid analysis liquid chromatography (RALC) has been used to assay a variety of compounds ranging from simple tablet formulations of acetaminophen[7] to combined products and more problematic compounds such as alkaloids,[8] antibiotics,[9] barbiturates,[8] and hormones.[10]

Alternatively, if the problem to be solved involves more complex samples or less routine usage such as that encountered during the discovery and development stages of a drug, then specificity, versatility, and flexibility are the more important factors. Some typical examples of these are encountered in: (1) the development of a reference standard material, (2) evaluating the purity of the drug substance, (3) stability testing of the active ingredient and its various formulations, and (4) measurements of bioavailability and pharmokinetics. In many cases gradient and multilevel elution approaches and combination column assays may not only be more convenient but necessary, in order to resolve a mixture of compounds produced via a complex synthetic route or if the target compound is a natural product or is produced via a fermentation process. Additionally, gradient elution approaches may provide an important advantage in the detection of trace impurities, especially if they vary significantly in their structures and polarity.

Generally, most practising chromatographers understand how to make their hardware work effectively, and they have a reasonable empirical/working knowledge of how to systematically change conditions in order to effect a given separation, but they sometimes either fail to consider or choose to ignore relatively simple fundamental concepts that influence the reliability and ruggedness of their method. Many of the problems associated with assay instability, such as erratic or slow changes in solute retention and poorly formed or varying peak shapes, result from poorly designed procedures that may provide the desired resolution but are not optimized to minimize variability. Thus, this article addresses the topic of optimization, pointing out whenever possible strategies that improve performance, especially when the assay is to be transferred from a research setting to the quality assurance laboratory and used routinely to monitor production runs.

1.2 Important Physical and Chemical Aspects of the Analyte

Besides the general sample/problem considerations noted above, a fundamental understanding of the physical and chemical aspects of the analyte are important in the systematic design of a reliable method. The first question that should always be asked in adopting an HPLC strategy should be ''is a liquid chromatographic approach the best solution?'' If the sample is thermally stable and volatile, then the answer for most analytes is no. For these types of analytes, methods based on gas chromatography are likely better approaches in terms of cost, simplicity, and reliability. However, if volatility and thermal stability are concerns, then liquid chromatography has been and continues to be the preferred approach in a majority of cases.[1–3] A working knowledge of the analyte's solubility in different solvents and its molecular properties in terms of size, structure, and equilibrium characteristics is important in selecting the overall separation and detection approaches, in choosing the column and eluent, and if necessary in fine-tuning the method in terms of the secondary modifiers needed. Likewise, an understanding of the possible contaminants and by-products that may arise during the chemical synthesis or isolation steps and of degradation products that may be formed as the result of drug instability or drug excipient and package interactions are important in validating assay specificity.

In the general design of a separation, given a series of closely related analytes, it is important to identify that portion of the solute which contains the structural differences and to enhance their interactions with the stationary phase. In some cases these are easily recognized; however, with increasing molecular complexity or with structurally dissimilar compounds, the problem becomes more difficult. As the approaches most often used in pharmaceutical analysis generally involve some form of RP separation, an important item of additional information is the protonation and deprotonation characteristics of the analyte. Although there may be a number of reversed-phase liquid chromatography (RPLC) conditions that will produce a satisfactory separation, some are preferable based on assay ruggedness, cost, and ease of use. It cannot be over emphasized that many of the commonly encountered

problems are associated with the solute and the stationary phase in terms of simple equilibrium considerations. Examples of these types of problems are fluctuations in the retention factor, k', and poorly formed peaks when RP separations are carried out at or near a solute's pK_a, and significant peak tailing for solutes which interact strongly with residual silanols. The logical selection of eluent additives, such as buffers, ion-pairing compounds, and masking reagents, requires a general understanding of the equilibria that govern the solute and its interactions with the stationary phase as well as knowledge about the nonideal nature of the stationary phase and residual silanol activity.

Shown in Figure 1 is the RP separation of a series of important pharmaceutical additives carried out using a conventional short (4.6 mm internal diameter × 30 mm) octadecyl column.[8] Figure 2(a) is the same separation using identical eluent conditions on a higher-efficiency wide-bore (7.0 mm internal diameter × 30 mm) RA column. In performing this latter separation, the flow rate of the eluent was adjusted to give an equivalent linear flow velocity to that used in Figure 1. The accompanying chromatograms (Figures 2b and c) illustrate how analysis speed can be enhanced by simple increases in flow rate.

Under the RP conditions used in Figures 1 and 2, the differences in retention of the ester homologs of *p*-hydroxybenzoic acid are governed by the interactions of the alkyl portion of the compound and the immobilized alkyl chains of the bonded octadecyl phase. The relationship between retention and size (i.e. carbon number) of the aliphatic portion of the paraben homologs is logarithmic, and a plot of ln k' against the carbon number is linear with a slope related to the incremental methylene selectivity.[11] The substitution of a series of $-CF_2-$ units in place of methylene units also results in similar incremental group additivity.[12] The predictable nature of retention for homologs is illustrated in Figure 3

Figure 1 RP separation of paraben homologs under RA conditions; column 4.6 mm × 30 mm octadecyl. (Redrawn from ref. 8 with permission.)

Figure 2 RP separation of paraben homologs under RA conditions; column 7.0 mm × 30 mm octadecyl. Linear flow velocities compared to that used in Figure 1: (a) same; (b) ×1.5; (c) ×2. (Redrawn from ref. 8 with permission.)

within a given column and between columns packed with similar stationary phases. Nonionizable homologs, like the parabens, are often useful as internal standards as they cover a range of predictable retention times under various eluent pH conditions, and they have similar detector

Figure 3 Plot of ln k' versus carbon number: (a) for the chromatogram shown in Figure 1; (b) for the chromatogram shown in Figure 2.

Figure 4 Gradient profile for the separation of the compounds given in Table 1: carrier solvent, *n*-hexane with 0.25% acetic acid; gradient solvent, 2-propanol with 0.25% acetic acid; solid vertical lines, retention times for later-eluting compounds; dashed horizontal lines, amount of polar modifier in eluent when the compounds elute.

responses. Similar linear relationships are obtained for other classes of compounds including ionizable solutes by controlling their deprotonation. This topic is discussed in greater detail in section 3.2.

Structural features, such as the addition of a polar group (e.g. a hydroxyl group), decrease the overall hydrophobicity of the solute and hence decrease retention under RP conditions. These same features result in increased retention under NP conditions. This is illustrated by the data shown in Table 1 for the anti-inflammatory drug tolmetin and related compounds.[13] Comparing the retention data (i.e. elution order) of compounds b, c, and f, which differ only by the substituent at the R_1 position, the greater interaction of the carboxyl group requires a stronger eluent (8.6 min into the gradient profile shown in Figure 4) compared to the corresponding methyl and ethyl esters that elute at the initial mobile phase conditions (1.2 and 1.6 min into the gradient). Although not shown, these same three compounds should be easily resolvable under RP conditions but in the reverse order with the

Table 1 Influence of structure on the gradient elution separation of a nonsteroidal anti-inflammatory drug and related compounds under NP conditions

Compound[a]	R_1	R_2	R_3	Retention time (min)
b	$-CH_2COOC_2H_5$	—H	$CH_3-C_6H_4-CO-$	1.2
c	$-CH_2COOCH_3$	—H	$CH_3-C_6H_4-CO-$	1.4
d	$-CH_2COOH$	—H	—H	3.4
e	—COOH	$CH_3-C_6H_4-CO-$	$-CH_3$	3.4
f (tolmetin)	$-CH_2COOH$	—H	$CH_3-C_6H_4-CO-$	8.6
g	$-CONH_2$	$CH_3-C_6H_4-CO-$	$-CH_3$	11.9
h	$-CH_2COOH$	$CH_3-C_6H_4-CO-$	—H	15.6
i	$-CH_2CONH_2$	—H	$CH_3-C_6H_4-CO-$	17.8
j	$-CH_2CONH_2$	$CH_3-C_6H_4-CO-$	—H	21.8

[a] 
same predictable incremental methylene additivity, as discussed above, once the carboxyl group's deprotonation is suppressed in the case of the parent acid, tolmetin.

The separation summarized in Table 1 is an example of the resolving power of NP methods for structurally similar compounds containing polar substituents. Although NP methods have become less popular because they are more susceptible to retention variability and column fouling, these types of problems can often be minimized. Approaches for doing this are discussed in greater detail in following sections. Under certain conditions, such as the separation of *cis* and *trans* isomers, NP methods may be the best choice.

1.3 Selection of the Separation Mode

The selection of the appropriate separation mode, whether it is based on an RP, NP, ion exchange chromatography (IEC), or size exclusion chromatography (SEC) mechanism, is dependent on the solubility and size of the analyte. In some cases, such as the analysis of common inorganic ions, the choice may be relatively straightforward, the methodology almost turnkey (such as the analysis of cations or anions via ion chromatography (IC)) and the retention predictable.[14] By far the most common application of IC is for measuring inorganic ions and it has been applied to a variety of products including injectable solutions, nutritive liquids, and vitamin formulations.[1–3] Similarly, the application of size exclusion methods have, to a large extent, been used for molecular weight characterizations and determinations of additivities (e.g. polyethylene glycols[15] and microcrystalline cellulose[16]) or to study the properties of a few individual compounds (e.g. the chemical stability of insulin[17]). More recently SEC usage has been increasing with the emerging interest in the development of novel type pharmaceuticals (e.g. polymeric drugs[18]) and biotechnology products from peptides, proteins, and DNA. Some recent examples where it is used include determination of the purity and homogeneity of recombinant hepatitis B virus antigens,[19] the analysis of acidic fibroblast growth factor in viscous formulations,[20] and the purification of plasmid DNA for cancer gene therapy.[21]

Another increasingly important problem is the stereochemical purity of pharmaceuticals, as numerous pharmacologically active agents are chiral and their two enantiomeric forms usually exhibit different physiological properties. Typically, three chromatographic approaches are used to resolve chiral pharmaceuticals:

- the preanalysis conversion of the enantiomers to diastereomers followed by their separation using achiral stationary and mobile phases;[22]
- the direct resolution of the isomeric pairs using achiral stationary phase with a chiral mobile phase additive;[23]
- the direct resolution of the enantiomers on a chiral stationary phase (CSP).[24]

Of these approaches, the latter has become the most popular because of ease and convenience, as well as availability of a host of CSPs. These can be classified into five major groups:[25,26] (I) Pirkle-type (donor–acceptor) phases, (II) inclusion (chiral cavity) materials, (III) helical polymers, (IV) ligand exchangers, and (V) immobilized peptides and proteins. In the latter instance, chiral recognition is a natural property of biological molecules, and when they are properly immobilized, either by physical adsorption or by covalent attachment, some if not most of their indigenous binding affinities are preserved. Of the reported separations being carried out, many employ columns with type I and type II packing. Although all of the above approaches and examples are important, further consideration of these topics is beyond the general scope and emphasis of the current article.

Although most small multifunctional-containing analytes can be separated by the use of either RP or NP conditions, RPLC is typically the route of choice, as noted earlier. This tendency has arisen based on practical concerns such as greater column ruggedness and ease of clean-up of RP packings, and operational considerations such as often longer equilibration times and instability of NP packings, even though in many cases the actual ability of NP approaches to resolve target compounds may be better. On a thermodynamic basis the problems associated with NP methods are the result of larger heats of adsorption (ΔH) that are two to three times greater than the corresponding ΔH values for solutes interacting with bonded alkyl phases. In extreme cases, for highly polar and larger molecules that contain many strongly interacting groups such as amine, amide and hydroxyl functionalities, irreversible or nearly irreversible sorption many occur.

Under NP conditions, two of the most commonly encountered problems are erratic fluctuations in retention and slowly drifting retention. In many instances these undesirable effects are due to short-term variations in laboratory temperature and slow column equilibration rates, respectively. In the first instance erratic changes in k' can be minimized through appropriate temperature control of the column and eluent. In general for most RP applications a $\pm 1\,^{\circ}C$ variation in laboratory temperature (i.e. change in the column temperature) will result in only a small variation in k' (<3%). However, under NP conditions it is not unusual to obtain two to three times this change and under certain conditions even an order of magnitude difference may be observed through significant

polarity changes in the sorbed layer of solvent present on the surface.[27]

The need for temperature control is especially important when NP separations are carried out on polar surfaces such as silica or alumina when using nonpolar carrier eluents (e.g. hexane and small amounts of a highly polar modifier such as an alcohol). These same types of conditions lead to slowly drifting retention, as the packing material may require hundreds of column volumes of the eluent to pass through it to reach equilibrium. This effect is illustrated in Figure 5(a) for a standard 4.6 mm i.d. × 250 mm silica column using *n*-hexane as the carrier eluent and modifying it with varying amounts of three polar alcohols. The curves were generated assuming a simple single-site titration-type adsorption model, an eluent flow rate of 1.0 mL min^{-1}, and a column containing 4 g of silica with surface area of 500 m^2 g^{-1} and five silanol groups per 100 A^2 available as adsorption sites. As it is not uncommon to use small quantities (<1%) of an alcohol modifier to obtain useful k' values, several hours may be needed for the column to reach equilibrium. The horizontal line in Figure 5(a) shows the time needed for the column to reach equilibrium using 0.5 vol% methanol, ethanol, and propanol (2.3, 3.2, and 4.2 h, respectively). Figure 5(b) illustrates this same effect as a function of three different column sizes. An even worse scenario in terms of long equilibration times occurs when hexane or another nonpolar solvent is used alone, due to the presence of trace amounts of dissolved water. This arises because a completely dry silica surface is significantly more retentive of polar compounds than a surface that is fully hydrated. The equilibration time problem often can be minimized if an adequate separation can be developed using an eluent containing larger quantities of the polar modifier and by more careful control of temperature and surface hydration.

As many pharmaceutically active compounds are water soluble and are relatively small to intermediate in size, in a majority of cases they can be resolved more conveniently using RP methodology. By far, the more common approaches employ alkyl-bonded phases in combination with binary hydro-organic eluents. Further, as a majority of the pharmaceutically active compounds contain ionizable groups, such as carboxyl, amine, and amide functionalities, it is necessary to control the pH of the eluent. In the simplest case, where only a single group or at least similar groups are involved, it is advisable to carry out the separation where the solute exists predominately in its uncharged state. This topic is considered in more detail in section 3.2. Generally, this simple strategy works better for acidic compounds than for bases because of equilibrium considerations and pH limitations of the stationary phase being used to carry out the separation. A working eluent pH range for most silica-based materials is 3–8.5. For short periods of time or when using some of the sterically stabilized bonded phases, this range may be exceeded. However, in doing this, it should be recognized that once phase-loss begins, it proceeds at an increasing

Figure 5 (a) Predicted equilibration rates under NP conditions for a 4.6 mm inside diameter (i.d.) × 250 mm column (i.e. containing 4 g silica with a surface area of 500 m^2 g^{-1} and five silanol groups per square nanometer). The eluent is *n*-hexane with varying amounts of (curve a) methanol, (curve b) ethanol, and (curve c) propanol as the polar modifier. (b) Predicted equilibration rates under NP conditions using *n*-hexane with 1% methanol as the modifier on columns packed with the same material described in Figure 5(a) but packed into columns with dimensions of (curve a) 2.3 mm i.d. × 250 mm, (curve b) 4.6 mm i.d. × 150 mm, and (curve c) 4.6 mm i.d. × 250 mm.

rate as the underlying substrate undergoes hydrolysis. Initially phase-loss results in slowly decreasing retention and increasing peak asymmetry and, subsequently, it can lead to complete breakdown of the underlying silica matrix. The manifestation of this is column voiding and erratic peak shapes. Refilling the column with additional packing material may provide a short-term solution to some of the more severe peak-shape problems, but it will never return the column to its original level of performance as column breakdown proceeds by phase-loss and chemical and physical degradation of the porous matrix.

In cases where the analyte or analytes are very polar, their interactions with simple alkyl phases under RP conditions may not lead to sufficient retention to resolve the analytes. Under these conditions, alternate more polar phases, such as cyanoalkyl and aminoalkyl materials, may be useful. A good example of this strategy is the separation of simple carbohydrates using amine-type phases. Alternatively, very good separations of polar solutes sometimes can be obtained on unmodified materials, such as silica, using NP chromatography.

1.4 Establishing the Starting Eluent Conditions

There are two basic strategies for establishing the starting eluent conditions. One of these involves an isocratic approach and the other a gradient-elution approach. The isocratic approach starts with a solvent with high eluting power, which is systematically decreased by increments in subsequent separations. In the case of RP conditions, the eluent contains a high level of the organic cosolvent. In order of usage and increasing elute strength, the three principle organic cosolvents are methanol, acetonitrile, and tetrahydrofuran. It is not uncommon to start with nearly 100% of the organic component for highly hydrophobic compounds. For NP methodology, the scouting experiment begins with a high level of the polar modifier (say 20–30% 2-propanol) added to the nonpolar carrier eluent (e.g. hexane). In carrying out the isocratic approach, it is important that the eluting strength of the initial mobile phase is high enough so that all compounds to be separated will elute quickly from the column, and that changes in the eluent's composition are made systematically. For RP methods, a 10 or 15% decrease in the organic eluent component provides a rapid means of arriving at an appropriate range of starting conditions and, for NP eluents, halving or approximately halving the polar modifier's concentration provides an adequate change.

A useful quantitative scale (i.e. the eluotropic series) for selecting solvents is based on the work of Snyder and colleagues[28,29] who examined how strongly solvent molecules adsorb to polar substrates. Although this scale was developed initially for alumina, it has been modified for silica. Experimentally it is often helpful, once three or four experiments are carried out, to make a simple plot of $\ln k'$ versus the percentage of organic component in the eluent. An extrapolation of this plot, which in many cases is linear or nearly linear, provides a convenient way of predicting the retention profile of a compound over a broader range of eluent compositions or in fine-tuning the selection of a eluent between compositions tried. This is illustrated in Figure 6 for the separation shown in Figure 7.

When employing the gradient-elution approach as a scouting technique, one starts with a mobile phase of low eluting power and programs its strength to increase with time. Often a 10–15-min profile is a good scouting time.

Figure 6 Retention data for the RP separation shown in Figure 7: (a) shows changes in k' versus percentage methanol in the eluent; (b) shows changes in $\ln k'$ versus percentage methanol in the eluent.

Figure 7 RP separation using methanol–water as the eluent. The chromatogram was obtained with a 30 : 70 mixture. Changes in retention (i.e. k' and $\ln k'$) versus eluent composition are given in Figure 6.

From the gradient profile it is possible to predict starting conditions. This is illustrated by the gradient profile shown in Figure 4 and the respective data summarized in Tables 1 and 2 for the NP separation of tolmetin.[13] The predicted starting conditions from an extrapolation of the gradient at the time a particular solute elutes from the column is listed in the last column of Table 2. The published isocratic conditions are summarized in column two. The predicted and actual conditions are in good agreement. Although not illustrated, this same strategy also is applicable for the selection of starting RP isocratic conditions from a gradient profile that is run from high aqueous conditions to high organic conditions.

In using either the isocratic or gradient approach to predict an initial set of mobile phase conditions, the practicing chromatographer is faced with the following question: ''How does one know if all compounds elute from the column?'' Given a known set of analytes to be resolved, this is easily evaluated. However, given a truly unknown sample or an analyte in a complex matrix, this question is more difficult to answer. Unknown/ghost peaks or slowly drifting baselines often reflect the elution of highly retained compounds. It is often advisable to use thin-layer chromatography (TLC) as a quick screening tool. Under most conditions, if a compound shows some level of migration (even if it is only a very small amount) under a given set of TLC development conditions, then it will be eluted from an equivalent HPLC stationary phase using a similar mobile phase.

1.5 Isocratic versus Gradient Methods

Although it is not always possible to develop isocratic methods for every assay, they tend to be more reliable and less expensive and, as exemplified by the number appearing in the literature yearly compared to the number

Table 2 Reported and predicted level of the polar modifier (isopropanol) needed for the isocratic separation of the compounds in Table 1 under NP conditions

Compound[a]	Reported amount of polar modifier (%)	Retention time (min)	Predicted amount of polar modifier (%)
b	1	1.15	1
c	1	1.40	1

i	20	3.40	22
j	30	5.00	30

[a]

of gradient procedures, they are the first choice in simple-component assays. Additionally, in many cases they are carried out using relatively simple hardware, requiring the operator to blend the eluent off-line. Because of the popularity of the RP methodology, this operation most often involves the preparation of binary mixtures of either methanol and water or acetonitrile and water. For the trained chemist this is a very simple procedure of measuring a known amount of each component and carefully combining them to arrive at the correct eluent composition. Likewise, to the trained chemist, volume changes due to mixing and preferential enrichment of one of the two components are well-known concepts if one component is added directly to the other in the same volumetric vessel. However, it is not uncommon for individuals who are less familiar with these concepts, first to add a given amount of one of the components to a graduated cylinder followed by the direct addition of the second component. This latter practice should be avoided as it can lead to mixing errors and measurable variability in the chromatographic separation. This is illustrated in Figure 8 for the separation shown in Figure 7 and the elution relationships in Figure 6. A 1-mL mixing error, shown by the dashed lines intersecting at points b, results in a very significant change in k'.

In cases where gradient methodology is necessary or at least more convenient, an added consideration in the optimization is selection of an appropriate profile in terms of linear, concave, or convex addition of the stronger

Figure 8 Change in k' for peak e in Figure 7 as a function of mixing error in the preparation of a 30 : 70 methanol–water eluent.

eluent component. Carrying out the initial separation with a linear gradient profile is often a good starting point. Based on this the gradient can be optimized to enhance the resolution of compounds in the initial part of the chromatogram by employing concave addition of stronger eluent components. Conversely, if the later peaks need additional resolution and the early peaks are well separated a convex gradient is used.

2 SAMPLE PREPARATION

2.1 Analyte and Matrix Considerations

One of the most challenging steps in any analysis, including those developed for assaying pharmaceutical products, is often conversion of the target compound into a form suitable for carrying out the chromatographic separation. In many pharmaceutical products, it is not unusual for the analyte to be present in combination with a variety of coadditives and, in the case of biological samples, at differing concentrations depending on source and disposition. This, coupled with physical constraints such as low volatility and thermal instability, has made HPLC methods the most widely used approaches for the quantization of pharmaceuticals in complex formulations and biologicals such as plasma, urine, and bile. Likewise for these same reasons, RP chromatography is especially well suited for these types of samples due to its ability to separate the analyte of interest from a wide range of contaminants. Nevertheless, sample pretreatment steps are usually necessary in order to convert the analyte into a form where the active ingredient is present at suitable concentrations and/or is free of contaminants and particulate matter that can interfere with the separation or damage the column and hardware. Even in cases where the separation can be carried out almost directly, (i.e. for formulations that can be chromatographed after a simple dissolution or dissolution/centrifugation steps) more extensive sample clean-up may be advisable in order to extend column lifetime. Ideally, the pretreatment steps should be rapid and inexpensive. Alternatively, in certain instances it may be more cost-effective to use a precolumn or to sacrifice column lifetime for speed and convenience.

2.2 Sample Work-up

In selecting the best set of pretreatment conditions, the analyst must first consider the physical state of the sample and its complexity. Clear liquids and capsules (i.e. analytes contained in a matrix that is free of particulate matter, dyes, and other coadditives) are generally the simplest types to analyze as either an aliquot of the liquid or a known amount of the powder can be diluted with the mobile phase or a compatible solvent containing an internal standard. Single-dosage forms such as capsules and tablets are analyzed either directly (i.e. to evaluate tablet-to-tablet uniformity) or after they are ground into a fine powder in order to obtain a homogeneous and representative sampling (i.e. composite assays). Many times the resulting formulations are dissolved in a suitable solvent (i.e. a solvent where the analyte is readily soluble and which is miscible with the mobile phase) and any suspended materials removed by centrifugation or filtration. Subsequently, a known aliquot of the supernatant or filtrate is diluted using a solvent containing the internal standard. Selection of an appropriate internal standard generally involves finding a compound that is similar in structure to the analyte and one that elutes near it in the chromatogram. As noted above, for RP methods a methyl homolog is often a good choice, if available, because it will have similar detection properties to the analyte and its retention will be predictable. If the homolog selected contains a larger number of carbon atoms than the analyte, it will elute later in the chromatogram. Conversely, if it has fewer carbon atoms, it will elute earlier. Likewise, a structurally identical or similar compound containing a hydroxyl group is also a good candidate for an internal standard and should elute more quickly than the analyte under RP conditions.

More complex samples typically require greater preparation, such as the removal of particulate matter by centrifugation or filtration or matrix proteins from biological media via precipitation with acetonitrile, ethanol, or trichloroacetic acid. These pretreatment steps are usually followed by some type of extraction in order to further isolate the analyte from soluble formulation coadditives

or biologicals that will either interfere with the assay or foul the column. Traditionally, liquid–liquid extraction has been the method employed most often, and for many applications this continues to be a useful approach, especially for more concentrated samples and when there are distinct differences in the solubility and equilibrium properties of the analyte from those of the contaminants. The disadvantages of liquid–liquid extraction procedures are that they are time-consuming and utilize relatively large volumes of solvents which can be expensive to purchase. Similarly, disposal of the solvent can add considerable cost to the assay and, for more dilute analytes, additional concentration steps (e.g. evaporation) often are required prior to injection of the analyte.

Alternatives to liquid–liquid extraction include adsorption and partitioning methods to concentrate the analyte from the matrix. Partitioning methods, particularly modern solid-phase extraction (SPE), have become popular and increasing in use because they remove particulate matter with concomitant sample concentration, can be carried out on small sample volumes, and are applicable to a wide variety of samples in terms of their physical and equilibrium properties. These are attractive features, especially for biological fluids that are limited to small volumes. A further advantage of SPE is that it typically can be carried out rapidly using minimal volumes of the elution solvents. Further discussions on this topic may be found elsewhere.[30,31]

The SPE technique is performed using small, disposable cartridges filled with 100–1000 mg of inexpensive sorbents that are available in a wide range of polarities and separation modes, analogous to HPLC phases. NP (silica and alumina), bonded NP (diol, cyano, and amino), RP (phenyl, octyl, octadecyl), cation (carboxylic acid, sulfonic acid, aromatic sulfonic acid), and anion (primary and secondary amino, quaternary amine) exchange, and size exclusion cartridges are commercially available from a number of vendors who also provide technical support.

Choosing an SPE sorbent is analogous to selection of an appropriate HPLC packing and depends on the solubility and equilibrium characteristics of the analyte as well as those of the sample matrix. Materials for SPE are chosen such that the analyte(s) of interest is either retained while the impurities pass through the cartridge or, conversely, the analyte(s) passes through the cartridge and the impurities are retained. The first approach is often preferred, because it can be used to purify and concentrate the analyte in one step. In the sample-retained mode, when the analyte is more hydrophilic than the sample matrix, NP-type sorbents are logical choices. Under this set of conditions, highly polar analytes are retained while less polar impurities can be made to pass through the cartridge. However, when the analyte is more hydrophobic than the sample matrix RP sorbents will selectively retain it with high efficiency and unwanted polar interferences can be made to elute. The reverse strategy is applicable when operating in the analyte-nonretained mode.

3 METHODS OPTIMIZATION

3.1 General Trends

Since the late 1970s an important trend in the area of pharmaceutical development has been the ever increasing use of HPLC, especially RPLC.[1–3] Thousands of compounds are analyzed daily by RPLC and new agents are continually under development which will use RPLC because of its ruggedness compared to other separation modes such as normal-phase liquid chromatography (NPLC), the solubility of many drugs in hydro-organic eluents, and the selection and optimization of conditions are easier. A close inspection of the recent pharmaceutical literature[1–3] reveals that by far the most typical set of RP conditions used employ either 150- or 250-mm columns packed with octadecyl or octyl bonded phases. These are used in combination with an isocratic mobile phase prepared from either water–methanol or water–acetonitrile and with the addition of secondary compounds to control solute ionization and to correct for nonideal surface effects.

3.2 Controlling the Chemical Equilibria

The most often used eluent additives are simple buffers, added to control the protonation and deprotonation of ionizable compounds and hence their retention properties. This is easily illustrated by the separation of a series of simple fatty acids with the general structure RCOOH. As these homologs contain the same functional group but again vary only in terms of the length of the alkyl chain, one would want to enhance (maximize) the interaction of the alkyl chain with an alkyl bonded phase by controlling the solute's dissociation. Experimentally, this is accomplished by adjusting the pH of the eluent to about 1–1.2 pH units below the pK_a of the carboxyl group which is approximately 4.7. When the eluent is buffered to 3.5–3.7, the solute exists predominately in its protonated, uncharged, form and its retention is governed by strong interactions between the nonpolar alkyl portion of the molecule and the immobilized alkyl chains of the bonded phase. There are many examples of pharmaceutically important agents which can be conveniently separated via relatively simple RP methodology by controlling the eluent's pH. These range from common products such as aspirin and ibuprofen to related analgesics or anti-inflammatories such as fenbufen, flurbiprofen, ibufeac, ketoprofen, and the anticonvulsant valproic acid.

Figure 9(a) illustrates the relationship between retention and pH for simple monoprotic organic acids. In the deprotonated form ($RCOO^-$), the solute elutes quickly from the column, whereas in the protonated form (RCOOH), it is retained to an increasing degree based on the aliphatic portion of the molecule. The mirror image of this behavior is observed for basic solutes.[32] In the fully protonated form, the relationship between retention and size (i.e. the carbon number) of the aliphatic portion of the homolog is logarithmic. A plot of ln k' versus carbon number is linear with a slope related to incremental methylene selectivity (Figure 9b).[11] Similar relationships also are obtained for other classes of solutes and the retention for a given series is often easily predictable from a simple plot of ln k' against the carbon number. The substitution of a series of nonpolar groups in place of methylene units also results in similar incremental additivity.[12] Likewise, an increase in the hydrophobic character of a series of homologs, such as through the addition of an aromatic ring, results in increased retention as illustrated by the parallel relationship that is offset to higher retention values for the alkyl phenols (Figure 9b, line a) compared to the fatty acids (Figure 9b, line b).

A simple rule is that by decreasing the charge (i.e. by dissociation) of the solute under common RP conditions one increases the interaction of the solute with the stationary phase, hence increasing retention and the possibility of resolving like compounds. As such, the preferred set of conditions for the separation of the compounds shown in Figure 9, as well as with other simple cases where only a single monoprotic group is present (such as the acid drugs shown in Scheme 1) or at least similar groups are involved, is in the plateau region of the curves. However, once the eluent pH is adjusted to this region, further adjustments to lower pH will have little effect on the quality of the separation, but will lead to increased chances of phase instability and decreases in performance of the column. Unfortunately in some cases, because of column stability considerations, the pH of the eluent cannot be adjusted low

Figure 9 Retention properties of simple monoprotic organic acids: (a) influence of eluent pH; (b) chain-length effect for different homologs.

Scheme 1

enough or high enough to fully protonate or deprotonate the solute. A working range for most silica-based bonded phases, is 3.0–8.5. In cases where the solute's equilibrium cannot be adequately controlled within this range, an ion-pairing reagent can be added to the eluent to control the solute's ionization. The most commonly used of these are alkyl (often C_5 to C_8) sulfates and sulfonates, and tetraalkyl (up to C_4) ammonium salts. Although the mechanisms involved in ion-pair separations are complex, its use on an empirical basis is relatively straightforward. The retention of the ionized solutes increases with increasing size of the alkyl portion of the ion-pair salt and conversely decreases with decreasing size.

As the sample becomes more complex in terms of the presence of multiple functionality and other structural features, it is often not possible to predict in advance many of the subtleties controlling retention. Considering some of the related nonsteroidal analgesic/anti-inflammatories appearing in Scheme 1, it is possible to predict that ibufeac will elute before ibuproben, as the molecules are structurally very similar except that ibuprofen contains an additional methyl carbon. However, it is much more difficult to predict how long indomethacin will be retained compared to tolmetin or the elution order of ketoprofen, fenoprofen, and flurbiprofen. Nevertheless, for the latter set of compounds, because they are structurally similar, it is reasonable to suggest that an assay developed for ketoprofen might be a useful starting point for fenoprofen. Additionally, it is reasonable to suggest that the pH of the eluent for separating the first six compounds in Scheme 1, as well as the remaining more complex structures should be about 3.5, as the only important structural feature requiring eluent buffering is the carboxyl group.

3.3 Nonideal Column Effects

Irrespective of the synthetic routes used to produce silica-based packings, an important controlling parameter inherent to all of these types of phases is the nature of the substrate surface (i.e. its chemical and structural heterogeneity).[33] Porous silica is an amorphous material with a three-dimensional structure that contains several types of polar silanol groups on its surface.[34,35] The distribution of these groups and morphology determine the extent and heterogeneity of the resulting bonded phases. The number and distribution of silanols change depending on the synthetic route that is employed to produce silica, as well as post-synthesis processing (i.e. thermal treatment and rehydration) to mechanically stabilize the material. Additional information on the physical and chemical properties of silica may be found elsewhere.[36,37]

When silicas are produced, it is not unusual to obtain materials that are equivalent based on an examination of their macroscopic properties, such as total number of silanol groups, surface area, porosity, etc. yet dramatically different in terms of microscopic heterogeneity which influences the nature of bonded phases produced from such materials.[38] To the practicing chromatographer, this problem manifests itself as manufacturer to manufacturer and batch to batch differences in column performance for a given stationary phase. Additionally, this problem is exacerbated for solutes that have polar functional groups that can interact strongly with residual silanols such as amines and heterocyclics. These are not uncommon types of compounds encountered on a daily basis in the pharmaceutical industry.

In order to minimize the residual silanol problems, one of four approaches is generally used, these being postreaction end-capping, preparation of sterically blocking phases, electronic manipulation of the attached surface groups, and the use of mobile phase additives. End-capping involves a resilanization of the column with a small reactive silane such as trimethylchlorosilane following the initial bonding process. The second approach utilizes surface ligands that can sterically block silanol accessability.[39–41] The third approach, electronically manipulated phases, involves imbedding a functional group within the bonded chain's interior that can interact with neighboring residual silanols (e.g. alkylamide phases).[42–46] Each of these three approaches has allowed manufacturers, as well as researchers, to prepare columns with enhanced chromatographic performance. Unfortunately, not all peak-tailing problems have been eliminated by these and, as columns age, the problem of exposed silanol groups increases even for high-performance bonded phases. Many of these unwanted effects can be eliminated or at least minimized through the use of secondary mobile phase additives.

3.4 Use of Secondary Additives to Enhance Performance

Although the performance of commercially available bonded phases has improved dramatically in recent years, there are still many RP applications where residual silanol activity leads to unacceptable chromatograms in terms of severely tailing peaks. Such problems can usually be addressed by the addition of compounds to the eluent that dynamically modify the surface by a competitive sorption mechanism, and hence act to suppress undesirable interactions that can arise between basic solutes and residual silanols. This process is sometimes referred to as silanol masking and the agents used to do this are strongly sorbing compounds (i.e. molecules that contain a polar head group and a nonpolar tail) that do not interfere with detection. The most commonly used compounds to

Figure 10 The RP separation of a simple test mixture of (peaks a) aniline, (peaks b) *N*-methylaniline, and (peaks c) *N*,*N*-dimethylaniline with 4.6 mm × 250 mm column packed with octyl-silica, with 60 : 40 v/v% methanol–water as eluent: (a) without masking agent; (b) 5 mM PFPA (*N*-(2-hydroxyethoxyethyl)-perfluoropropylamide) added as a masking agent. (Redrawn from ref. 48 with permission.)

mask silanol activity, and hence improve peak symmetry, are alkylamines;[47] however, in a few cases other compounds, such as perfluororalkyl surfactants, have been employed.[48,49]

The chromatograms appearing in Figure 10 illustrate the dramatic effect a masking agent can have on the separation performance of solutes (e.g. simple aromatic amines) that interact strongly with residual silanol groups. Both separations were carried out on a standard commercial octyl bonded phase using 60 : 40 methanol–water. However, chromatogram (a) was obtained without the addition of a masking agent and chromatogram (b) was obtained with a masking agent present in the eluent.[47]

Within the realm of pharmaceutical drug analyses, two techniques currently dominate the field. High-performance liquid chromatography (HPLC) is at the forefront, followed somewhat distantly by gas chromatography (GC). HPLC is more prevalent than GC owing mainly to the heat-labile nature of the majority of drug substances. Still GC continues to play a very active role. In comparison to HPLC and GC, combined, the frequency of use of other techniques is quite small. Perhaps the major reason for this is that chromatography not only involves qualitative and quantitative detection of targeted species, but also provides a medium for isolating these analytes from potential interfering impurities prior to measurement. The proficiency of this combination is unparalleled by any other blending of means to clean up a sample and detect

the target compound. These more prominent techniques are often complementary, although each has its own strengths and limitations. General guidelines are given to assist the chromatographer to elect HPLC and/or GC for a particular separation. Considerations for choosing hardware type and sizes, solid support and bonded phase are presented. Particular emphasis is placed on the latest, which is of primary importance for obtaining rugged methods. The reader is directed towards optimum phase selection based on the compound of interest's functional group type, or by its drug activity classification (e.g. barbiturate, cardiovascular, etc.). Assistance in developing new methods frequently arises when starting with an existing published method for a compound with similar structure. This article provides 514 references for more in-depth separation information. In addition, background knowledge on bonded-phase chemistry, chromatographic modes of separation, approaches to chromatographic chiral drug discrimination and processes for developing rugged methods is contributed.

1 CHOOSING THE SEPARATION TECHNIQUE – GAS CHROMATOGRAPHY VERSUS HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

1.1 Introduction

GC and HPLC are generally considered to be complementary techniques. Choosing one over the other is often dictated more by equipment availability[1] and familiarity than by which technique is better suited for a particular application. However, guidelines exist for the chromatographer to make educated choices for the optimum system, when both means are available. Traditionally, GC chromatograms have provided an order of magnitude more theoretical plates than HPLC, although newer HPLC columns packed with smaller particles approach GC performance in that regard. Higher theoretical plates enable easier separations of more complex samples that contain numerous constituents. A chromatogram containing about 15 peaks would be considered complex for most HPLC separations, but is more commonplace for GC chromatograms. HPLC is capable of *separating* a wider range of analytes than GC. Earlier, GC was capable of *detecting* a wider range of analytes with better sensitivity than HPLC. However, this advantage has diminished with the advent of light scattering detectors, and ''hyphenated technologies'' such as liquid chromatography/mass spectrometry (LC/MS)[2–4] and liquid chromatography/nuclear magnetic resonance (LC/NMR).[5] In fact, Gelpi[6] postulated that LC/MS is replacing gas chromatography/mass spectrometry (GC/MS) analyses for drug metabolism, therapeutic drug monitoring (TDM) and pharmacology, since the former is applicable to highly polar and larger molecular weight compounds without complicated derivatization and handling procedures.

There is evidence that HPLC is currently the more popular technique and is growing faster than GC. In a 1995 survey,[6] total HPLC instrument sales ($840.00 million) were higher than GC instrument sales ($575.00 million). A 1997 survey of analytical instrument end-users[7] reported that HPLC (1600 units) was the main technique used, followed by GC (1300 units). Other techniques, such as UV/VIS (ultraviolet/visible), electrophoresis, FTIR (Fourier transform infrared) and AA (atomic absorption) were less utilized than HPLC or GC. Around 50% of HPLC owners surveyed expected increased HPLC usage over the next five years.[8] In contrast, about half of the GC users considered their technique to be mature with few new applications emerging. Within the pharmaceutical industry, HPLC was the most commonly used instrumentation in the laboratory (35%) followed by GC (15%).[9] Pharmaceutical QA/QC (quality assurance/quality control) laboratories employed HPLC (49%) in higher percentage than GC (19%), and HPLC was expected to demonstrate a significantly higher growth rate than GC over the next five years.[10]

In reflection of the above surveys, this article focuses proportionally more on HPLC than on GC pharmaceutical separations. Nevertheless, it appears that GC will remain an important tool in pharmaceutical analyses for some time.

It is important to note that the references provided in this work are by no means an exhaustive coverage of the available literature for the given topics. Rather, they serve to exemplify distinguished points and provide starting conditions for the analyst in methods development of unique compounds.

1.2 Sample and Other Considerations

Perhaps the most important points in choosing between GC and HPLC methodology are the volatility and thermal stability of the sample. Nonvolatile samples are not suitable for GC analyses unless they are derivatized to a more volatile form. Gouw and Jentoft[11] estimated that only 15% of known compounds can be volatilized without thermal degradation. There are no such restrictions with HPLC, which is at least part of the reason for the increased popularity of HPLC over GC in pharmaceutical separations. Sample volatility is dependent on the composition and structure of the compound and its molecular weight. As a general rule of thumb, pharmaceutical chemicals above about 200–300 molecular weight and those containing polar functional groups are better suited for HPLC analyses.

Derivatization for GC analysis is accomplished by reducing a nonvolatile sample's polarity. Electrophilic and other derivatization reagents are commercially available from a variety of chromatography companies and are usually shipped in sealed ampules to prevent atmospheric moisture from deactivating the reagent. Some of the more popular reagents include silanes, acylation reagents and alkylation reagents. They react with compounds that contain exchangeable or active protons (protic samples), such as alcohols, thiols, carboxylic acids and amines, to form the corresponding ethers, thioethers, esters and amides, or with aldehydes and ketones to form oximes. In addition to increasing sample volatility, many derivatized samples also exhibit higher detection sensitivity, selectivity and chemical stability than the parent sample. Disadvantages in derivatized sample methodology include the added preparative time and expense, and the need to determine the percent yield of the derivatized product for quantitative measurements. Reproducible derivatizations may be particularly difficult with samples that contain more than one reactive site. By-products and side products may also co-elute and interfere with chromatographic peaks of interest.

Although not as prevalent as in GC, HPLC derivatizations are also occasionally performed. For strategies and synthetic methods in pharmaceutical HPLC sample derivatizations, see Ahwja[12] and Danielson et al.[13]

Although the analyte itself may be volatile, the sample matrix may preclude use of GC analyses. Nonvolatile components can build up within the GC column, affecting subsequent chromatographic performance, or even plug the column. Prepurification by solid-phase extraction (SPE), membrane filtration, flash chromatography and other procedures are viable options, but add to analysis time and cost.

Determining residual solvents in drug substances is an application particularly suited for GC analysis. Twenty-two common process solvents were determined by Kersten[14] and the results were not affected by weakly acidic, weakly basic or neutral drug matrices.

Analyte stability may play a role in the choice of technique. Heat-labile compounds may be more suited for HPLC than GC. GC may be more appropriate than HPLC for compounds that can potentially react with silica surface silanols. As discussed below (section 3.3), nonsilica HPLC phases are available to extend the useful range of HPLC packings. Notwithstanding, sample stability of analytes is often overlooked in methods development, but is often an important consideration.

1.3 Literature Comparisons

The complementary nature of HPLC and GC techniques is exemplified by the separation of atropine [51-55-8] and obidoxime [7683-36-5] parenteral solution, an emergency treatment for toxic organophosphates poisoning. Pohjola and Harpf[15] found that simultaneous GC analysis required tedious and time-consuming sample preparation owing to their different extraction properties, and obidoxime is thermally labile. Retention characteristics differed widely for the two components, making simultaneous HPLC analysis unsuccessful, even under gradient conditions. The authors settled for a GC method for atropine and an HPLC method for obidoxime.

Bile acids analysis generally gave identical results by GC and HPLC/UV (high-performance liquid chromatography/ultraviolet). However, Scalia et al.[16] chose HPLC as the more convenient system for routine analyses since it bypassed derivatization reactions required for GC analysis. GC was then used for verification of HPLC results.

Similarly, Guinebault et al.[17] picked HPLC as the faster and simpler technique for the determination of cicloprolol [63659-12-1]. The GC/EC (gas chromatography/electron capture) method gave somewhat lower levels of detection at $1\,ng\,mL^{-1}$ (compared to $5\,ng\,mL^{-1}$ for the HPLC fluorescence method), and was used for lower level samples.

Regarding TDM, Mehta[18] discussed several advantages of HPLC over GC. The former technique was considered to be quicker and more widely applicable. Sample cleanup was simpler, which is important for TDM. GC methods are often limited to 1-μL injections, whereas up to 100 μL can be injected on an HPLC column. Furthermore, HPLC is more adaptable to automation than GC.

Qualitative and quantitative results by HPLC analyses of nitrosamines were found to be in agreement with GC analyses as reported by Röper.[19] HPLC/UV detection of diethylnitrosamine at 254 nm matched the sensitivity of GC/FID (gas chromatography/flame ionization detection). The significant advantage in this study was that the HPLC method could be run in half the time that it took to run the GC method.

A review of HPLC and GC analyses of basic neurotransmitters and their metabolites was recorded by Yi and Brown.[20] Although the report summarized work published before LC/MS reached a level of commercial importance, HPLC was already seen as gaining on GC/MS, in use for routine analysis of diseases.

Suitability studies between HPLC and GC techniques, such as those described above, are not directly comparable. Contrarily, the conclusions obtained from such an endeavor rely heavily on the particular equipment, conditions and methodology employed. They serve only to introduce the types of problems that might be encountered in investigating a particular HPLC or GC technique. In a practical sense, the actual choice of one technique over the other might best be accomplished by

finding published work on how similar mixtures were analyzed, keeping in mind the considerations discussed above (see section 1.2).

1.4 Ideal Methods Development

The ideal chromatogram presents impurity peaks eluting at or near the solvent front, followed by peaks of interest emerging with baseline resolution (defined by ASTM (American Society for Testing and Materials) as being $R_s = 1.5$) and no more. This scenario provides the best approach in obtaining simple, relatively inexpensive, rugged, reproducible and fast methods. Although ''real'' sample mixtures rarely can be separated so perfectly, the professional chromatographer should strive to procure quality in developing as close to the ideal method as possible. Many pharmaceutical methods are Food and Drug Administration (FDA)-regulated, placing severe restrictions on analytical modifications. As a result, analysts are often locked into running poor methods for years to come. It is very time-consuming and expensive to revalidate or develop a new method. The prudent choice is to develop good methods up front, although the necessary time often is not afforded to the analyst. As a result, analytical laboratories specializing in cGMP (continuous good management practices) methods development have sprung into existence, particularly in the 1990s, to provide this needed service. The most versatile laboratories have expertise in both HPLC and GC for acquiring sound methods. For strategies on methods development, see section 5.3.

2 COLUMN SELECTION

2.1 Tubing Choices

Stainless steel (SS) tubing is the most widely used tubing for HPLC columns. They are rigid and can easily withstand packing pressures that typically go up to 10 000 psi (6.9×10^7 N m^{-2}). The material is relatively inert to a wide variety of solvents and chemicals. A smooth internal diameter (ID) of the SS tube can be honed, which is desirable for packing high-efficiency columns. Root mean square (RMS) units are used in measurement of smoothness of the tubing ID, by a profilometer instrument. A RMS of about 16 or better is standard for 4.6 mm or larger SS HPLC columns, 2-mm ID columns are generally 32 RMS, and 1-mm ID columns are usually 40 RMS or worse.

Reduced bore SS tubes of about 2 mm or less are more difficult to hone and quality control than larger bores. Some are coated with a glass lining, which may provide a smooth internal surface enabling higher efficiency in the packing process. Antithetically, the glass-lined tubes are somewhat susceptible to cracking, which critically inhibits packing good columns. Other commercial SS tubes are micropolished with an abrasive mixture that is forced through the column.

Particularly in some protein and peptide separations, polyetheretherketone (PEEK®) tubing is thought to provide a more inert surface than SS. PEEK® column frits (used to hold the HPLC packing material in the tube) may be employed in conjunction with PEEK® columns. Although PEEK® is a ''hard'' plastic, it is less rigid than SS and it is often more challenging to pack PEEK® columns with the same efficiency as SS columns.

A newer approach to produce smooth, inert HPLC tubes entails coating a proprietary silicone-containing layer of material known as Silcosteel® onto the ID of the SS tube. The strength and ruggedness of the SS tube is retained and excellent improvement in deactivation is realized. The coating treatment was originally developed for deactivating fused silica and flexible SS GC columns and also for air monitoring SS canisters, particularly for use with invasive sulfur-containing samples. Its use has been extended to deactivate bonded silica HPLC particles.

Early GC capillary columns, since the 1950s, were largely made of SS. They were rugged and flexible, but lacked inertness. Latter developments in packed glass columns improved inertness at the expense of being more fragile. In 1979, the more rugged and flexible fused silica tubing was discovered, which was considered to be a breakthrough in GC technology. Capillary fused silica columns are even more inert than glass columns. One limitation they do have is that they become brittle at temperatures exceeding 350 °C. Some improvements in thermal stability have been attempted by devising aluminum cladding or high temperature polyimides as an outer column coating. Another approach was the aforementioned invention of silica-lined, thin-walled, SS capillary columns.

2.2 Dimensions

Majors[21] reported in a 1994 survey that the 250 × 4.6-mm column (53.2%) is the most popular dimension used, followed by the 150 × 4.6-mm (40.9%) size. The 4.6-mm ID columns are popular partially because system peak bandspreading is less of a factor for large ID columns compared to small ID columns according to the relationship in Equation (1):

$$\sigma^2_{\text{total}} = \sigma^2_{\text{sys}} + \sigma^2_{\text{col}} \quad (1)$$

where, σ^2_{total} is the total bandspreading, σ^2_{sys} is the bandspreading due to HPLC system effects and σ^2_{col} is the bandspreading due to HPLC column effects.

Thus, as column ID decreases, the σ^2_{col} term becomes smaller and σ^2_{sys} contributes proportionally more to the total peak bandspreading. Columns down to about 3-mm ID typically do not require significant changes in an existing HPLC system to obtain peak efficiencies similar to a 4.6-mm ID column. However, column IDs of 2 mm or less may require changing the HPLC hardware to minimize the now dominant σ^2_{sys} term. This may include switching to narrower ID and/or length connective tubing, replacing the flow cell with one of smaller volume, and/or using a pump designed to deliver accurate slower flow rates.

Approximate optimum flow rates for the corresponding column ID are shown in Table 1. Note that regardless of the column ID, the linear velocity remains constant for optimum efficiency. The optimum linear velocity is about 0.15 cm min^{-1} in HPLC separations. This value can change slightly depending on the column packing material. The advantages of using smaller ID HPLC columns include solvent savings (Table 1) and increased sensitivity for samples of limited quantity.

Larger ID columns are desirable for semi-preparative (about 10-mm ID) and preparative (about 20-mm ID or larger) separations. Mobile phase and other chromatographic conditions are first explored on a smaller ID analytical column to save time, solvent and costs. After desirable conditions are found, increasing sample loads are run to determine the ''overload'' point. Overload is not strictly defined, but is relative to the needs of the analyst. It is the highest load that can be run before the desired separation is lost. For chemists pursuing 98^+% purity for drug candidate testing, near baseline conditions may be required. Alternatively, a marginal separation may provide the required purity level by the shave/recycling process (Figure 1).

Once the analytical column scouting work has been completed, the following calculations in Equation (2) and Equation (3) may be used to ascertain the corresponding flow rate and load, respectively, for the semi-preparative/preparative column chromatography runs:

Table 1 Optimum flow rates for HPLC columns of varying ID

Column ID (mm)	Optimum flow rate (mL min^{-1}) or normalized solvent usage (mL)
0.3	0.0043
0.5	0.012
1.0	0.047
2.0	0.19
3.0	0.43
4.0	0.76
4.6	1.0
7.0	2.3
10	4.7
20	9.5

Figure 1 Shave/recycling technique for a nonbaseline resolved preparative HPLC separation. Fraction 1, collect for >98% purity of first compound. Fraction 2, collect and recycle in subsequent injection. Fraction 3, collect for >98% purity of second compound.

$$F_p = F_a \frac{D_p^2}{D_a^2} \quad (2)$$

where F_p is the flow rate of preparative column, F_a is the flow rate of analytical column, D_p is the diameter of preparative column and D_a is the diameter of analytical column.

(Note that this calculation was used to determine the optimum flow rates in Table 1).

$$S_p = S_a \frac{D_p^2 L_p}{D_a^2 L_a} \quad (3)$$

where S_p is the sample load to inject on preparative column, S_a is the sample load injected on analytical column, L_p is the length of preparative column and L_a is the length of analytical column.

It is important to note that Equation (2) and Equation (3) do not necessarily hold true unless the packing material in the preparative column is identical to that in the analytical column. Some chromatographers prefer to use a larger particle diameter (for example, 12-μm preparative particles instead of 5-μm analytical particles) in preparative columns to reduce backpressure, and because of their lower initial cost. However, preparative separations using small particle sizes are not only feasible, but also can be advantageous. Substantially higher efficiency preparative columns can be obtained, and faster flow rates may be used without significant sacrifice of efficiency.[22]

The larger sample amounts injected on preparative columns may cause the UV (ultraviolet) signal to go off scale, even at maximum attenuation. If a nonlinear setting is not available on the detector, the signal may be reduced by setting the detector wavelength away from the UV_{max} (ultraviolet maximum) of the analyte.

Theoretically, column ID does not affect column efficiency. In practice, however, column IDs of about 2 mm or less are more difficult to pack and generally generate about 10 000–20 000 plates m^{-1} lower efficiencies than the corresponding larger ID columns. In contrast, theoretical plates increase in direct proportion to column length. Thus, a 200-mm length column should provide twice the efficiency of a 100-mm column, all other factors being equal. For routine analytical work, lengths of 150 mm or 250 mm are commonplace. Lengths of 50 mm or less are popular for fast separations and may be packed with smaller particle sizes to boost the efficiency lost by using shorter column lengths. Sizes longer than 250 mm may be utilized to gain any needed efficiency to attain a preferred separation. Size exclusion chromatography (SEC) prevalently uses longer columns or two coupled columns to attain desired separations.

Regarding GC columns, the ID choice is primarily based on the concentration range of the targeted analytical compounds. Overall sample concentrations may need to be adjusted to fall within the linear range of the detector being used. The column ID is then chosen that can function within that range. Table 2 includes suggested column IDs based on sample capacity. Resolving power (measured by plates m^{-1} or Trennzahl values) increases with decreasing ID (see Table 2). With very complex samples, the smallest ID column within the sample range capacity should be chosen. If samples are dirty, a wider ID column may be beneficial in reducing column plugging. Column IDs of 0.32 mm or 0.53 mm are recommended for splitless, direct or on-column injections to promote better sample transfer efficiency and increase quantitation. Instrument types and inlet systems may require certain flow rates, dictating the ID selection. Packed column GC inlet instruments are limited to 0.32 or 0.53-mm ID columns because their higher flow rates are essential to improve sample introduction, unless system modifications are introduced. Capillary injection systems accommodate any column ID Finally, instruments with sample valves and purge and trap inletting systems operate best with higher flow rates, which may be afforded by 0.53-mm ID columns.

Resolution increases with the square root of, and analysis time increases directly proportional to, the column length for isothermal separations. More than half of the columns used in laboratories are 30 m in length. Longer GC column lengths are standard for low-boiling complex mixtures, while shorter thicker filmed columns are popular in preventing peak tailing from highly active compounds. Shorter columns also tend to display lower bleed levels and have utility for fast separations of simple mixtures, or for extremely high-molecular-weight compounds.

2.3 Coverage and Film Thickness

Percent carbon values for HPLC bonded phases are frequently reported by commercial manufacturers as an indication of the hydrophobic retentivity of the packing. However, this can be deceiving. A better measurement is the coverage calculation, which in addition to percent carbon, also takes the particle's surface area into consideration. The coverage value furnishes a gauge of phase ligand density, hydrophobicity, surface silanol availability, mixed mode silanol activity and possibly phase stability. These points are addressed in more detail below. Of the coverage formulas used by chromatographers, perhaps the most precise calculation is that introduced by Berendsen and de Galan[23] as follows in Equation (4)

$$\text{Coverage } (\mu\text{mol m}^{-2}) = \%C \frac{10^6}{100 \times n \times 12.01 - (\%C \times (\text{MW} - 1))} \text{SA} \quad (4)$$

where $\%C$ is the percent carbon of bonded phase (measured by elemental analysis), n is the number of carbon atoms in one bonded ligand, MW is the molecular weight of bonded ligand and SA is the surface area of silica.

Table 2 Typical GC column characteristics[a]

Column ID	0.18 mm	0.25 mm	0.32 mm	0.53 mm
Helium (20 cm s^{-1})	0.3 cm^3 min^{-1}	0.7 cm^3 min^{-1}	1.2 cm^3 min^{-1}	2.6 cm^3 min^{-1}
Hydrogen (40 cm s^{-1})	0.6 cm^3 min^{-1}	1.4 cm^3 min^{-1}	2.4 cm^3 min^{-1}	5.2 cm^3 min^{-1}
Sample capacity	<50 ng	50–100 ng	400–500 ng	1000–2000 ng
Trennzahl values	40	30	25	15
Theoretical plates/m	5300	3300	2700	1600
Effective plates/m	3900	2500	2100	1200

[a] From Restek Corporation with permission.

Figure 2 Silanol proton loss consideration in formulating a bonding coverage calculation.

This formula addresses the fact that a proton was removed from the bonded silanol as depicted in Figure 2.

Coverage can also be an indicator of phase ratio (amount of solute in the stationary phase per amount of solute in the mobile phase). Increasing the phase ratio can, in turn, increase resolution by increasing the capacity factor term in the resolution equation (Equation 5). Higher coverage packings generally exhibit increased phase ratios, excluding situations where mixed mode separations play significant roles.

$$R_s = \frac{1}{4} \times \frac{\alpha - 1}{\alpha} \times \frac{k'_1}{k'_1 + 1} \times N^{1/2} \qquad (5)$$

where α is the selectivity, defined as k'_2/k'_1, k' is the capacity factor of the peak and $N^{1/2}$ is the square root of the number of theoretical plates for a particular packed column.

In GC separations, film thickness can be regarded as a reflection of the phase ratio. Thicker films are used for low-boiling compounds to increase retention and, thereby, resolution. Moderately thick films (1 or 1.5 μm) are utilized for samples that elute between 100 and 200 °C. Samples that elute up to 300 °C can be run on standard films (0.25 or 0.5 μm).

2.4 Stability and Reproducibility

Silica-based HPLC packings are still the most widely used phases. They possess excellent mechanical strength, are relatively inexpensive, can be easily modified to render desired chromatographic performance, and can be manufactured reproducibly with control of both particle and pore size distributions. One shortcoming is that they are limited to a pH range of about 2 to 7.5. Kirkland[24] reported that higher pH conditions hydrolyze the siloxane backbone, while lower pH conditions hydrolyze off the bonded-phase moiety. Acid hydrolysis typically results in a loss of chromatographic retention with repeated injections, as bonded phase is gradually liberated from the column. Base hydrolysis maintains retention since the bonded phase attachment remains intact, but abruptly loses efficiency, when the silica backbone finally collapses. Nevertheless, analysts continually push the pH limitations of silica in developing methods for difficult mixtures. Commercial column manufacturers have responded by developing technology to extend the useful pH range of silica packings. One strategy was to manufacture bulky side chains on the bonded phase in an attempt to hinder hydrolysis of the bonded phase sterically. The commercial product, Zorbax® Stablebond®, reportedly increased acid stability.[25] Another study applied larger 150-Å pore, pure silica particles ($1\,\text{Å} = 10^{-10}\,\text{m}$), and high coverage bonding chemistry to obtain essentially the same level of acid stability.[26] Advances in base stability of silica packings have also been reported.[27] In addition, nonsilica packings are used for methods run at pH extremes (see section 3.3).

An investigation into commercially available modified silica HPLC packings will reveal that, almost without exception, bonded phases are prepared with no less than three carbons between the reagent silicon atom and any heteroatom present in the reagent. Thus, there are 3-cyanopropylsilyl phases, 3-aminopropylsilyl phases, 3-glycidoxypropylsilyl phases, etc. The reason for this is that spacers of less than three carbons result in an inherently less stable compound. A review of the stability of bonded phases was published by Unger.[28]

There have been some claims that cyanopropyl bonded phases hydrolyze under acidic HPLC conditions to the corresponding propylcarboxylic acid as shown in Scheme 1. It is true that synthetic chemists use cyano functionality to mask the eventual preparation of carboxylic acid moieties. Still, the cyano hydrolysis in synthesis deprotection procedures[29] is persistently much more invasive than regularly practiced HPLC conditions. This author found no sign of cyano group hydrolysis of a cyanopropyldimethylhydroxysilane model under conditions ranging from pH = 2 to pH = 7, by proton NMR (nuclear magnetic resonance) or HPLC using chemical probes.

Scheme 1 Hypothetical acid hydrolysis of an HPLC cyano bonded phase.

Ester groups are susceptible to hydrolysis by acidic mobile phases, which should be avoided with both ester bonded phases and/or ester analytes. Whenever practical, ester solutes should be run under neutral pH conditions.

There are commercial phases that are not covalently bonded to solid supports, but rather are "ionically" coated onto the surface of particles. These phases, such as some chiral cellulose packings, are strictly limited to certain types of solvent exposure. Even slight amounts of solubilizing solvent can ruin a column.

Reproducibility of HPLC bonded phases is largely dependent on the replication of the bare silica. Bonding chemistry is also important. Monofunctional bonded phases are inherently easier to reproduce than di- and trifunctional bonded phases (see section 3.2). Some commercial difunctional and trifunctional bonded phases (see section 3.2) contain residual alkyloxysilane or chlorosilane functionality following bonding. Under aqueous mobile-phase conditions, these residual reactive groups might slowly hydrolyze, resulting in an unstable baseline (bleed) over a long period of time, with constantly changing chromatographic performance. Even if a stable baseline can eventually be obtained, reproducibility of this product under similar bonding tactics is customarily poor. Commercial polymeric aminopropyl phases, used for sugar/carbohydrate separations, are prime examples of this type of hydrolysis problem.

HPLC and GC bonding reagents should be purified of any catalysts used in their formation before attachment to silica. It is very difficult to remove them afterwards. Their presence may cause unstable baselines, peak tailing or possible catalytic decomposition of some analytes (e.g. proteins).

Column bleed in GC phases ordinarily is larger for thick films than thin films of the same coating. The phases have varying degrees of inherent thermal stability depending on their chemical nature. Manufacturers routinely list proper operating temperatures, which should be followed to prevent phase degradation. Tolerable residual bleed normally occurs even at low temperatures owing to trace amounts of oxygen, metals, catalysts and other impurities that slowly degrade the polymer film.

The reproducibility of commercial brand stationary-phase performance over several years, whether HPLC or GC, should not be taken for granted. Welinder et al.[30] describe some of the real-life enigmas associated with unannounced manufacturer's phase alterations over time. The authors stress the importance of validation, GMP (good management practice), SOP (safe operating procedures) and QA/QC for the column manufacturer, who should be treated as a contract laboratory.

2.5 Phase Type

Pharmaceutical methods development, whenever possible, should be attempted on a reversed-phase (such as a C_{18}, C_8, phenyl, etc.) column. This is due to the simple hydrophobic mode of separation that is most familiar to the chromatographer. Reversed-phase separations are often rugged, and columns are relatively inexpensive and readily available.

The C_{18} phase (also called octadecylsilyl, or ODS phase) was one of the first modified silica types prepared, owing to the availability of the starting material rather than for any specific scientific motive. Its use rapidly gained in notoriety during the early years of HPLC and it remains the most popular phase today.[21]

It is crucial to note that all commercial C_{18} phases are not alike. In fact, it can be favorably argued that no two C_{18} phases are alike. Figure 3 illustrates the vast possible differences in C_{18} brand column performance.

Shorter hydrocarbon chain reversed-phase columns may be used to reduce retention of highly adsorbed compounds. Phenyl phases add possible dipole:dipole or dipole:induced dipole interactions for another dimension in solute/stationary phase recognition. In particular, phenyl phases appear to have proficient selectivity of carbamates. Cyano phases are one of the best choices for basic pharmaceuticals, showing excellent peak shape and complementary selectivity to C_{18} phases. Cyano columns are also a good choice for steroids, and can be used under both reversed-phase and normal-phase conditions. De Smet and Massart[31] found the cyano phase to be so versatile for normal- and reversed-phase separations of basic drugs, that they used it exclusively.

A modified C_{18} phase engineered for use under high aqueous mobile-phase conditions is of particular interest in reversed-phase retention of polar solutes. Traditional C_{18} phases contain hydrophobic chains that may fold under such conditions to avoid the hydrophilic mobile phase surroundings.[32] Modified commercial C_{18} phases based on this concept adopt a similar fundamental strategy in introducing polar functionality close to the silica backbone. In this manner, the C_{18} chain, hypothetically, remains extended since there is a hydrophilic environment both in the mobile-phase volume and towards the solid support surface.

Newer reversed-phase columns include the intrinsically base deactivated (IBD) phases. They are categorized as those packings that contain a polar functional group within, or intrinsic to, the hydrocarbon chain (see Figure 4). The intrinsic heteroatom(s) apparently is involved in deactivating active surface silanols that would otherwise cause undesirable peak tailing of basic compounds.[32] The heteroatom also appears to play a major role in selectivity, as reversals in elution order are

Figure 3 Hydrophobic retention differences of some commercial C_{18} phases. (From Restek Corporation with permission.)

Figure 4 IBD packings. X is a polar group.

commonplace compared to C_{18} phases. Solute mixtures of acids, bases and zwitterions can often simultaneously be separated with good peak shape for all solute types using simple mobile-phase conditions. Separations on this phase are somewhat more affected by small differences in mobile-phase composition than C_{18} phases are, which may make developed methods slightly less rugged. However, some of these phase types show immunity to chain folding, similar to the modified C_{18} phases described above. A few IBD phases are commercially available.[32]

Another variety of reversed-phase column is the halogenated stationary phases discussed in section 5.6.

The most prevalent normal-phase columns employed in the pharmaceutical industry are the amino phase columns for sugar-containing drugs, saccharides, and so on, and the diol phase for polar compounds. The latter phase is regularly used in SEC, especially for proteins and large peptides (see section 4).

Ion-exchange columns are used for highly polar, ionizable drugs that cannot be retained by reversed-phase columns. Weak anion-exchange (WAX) columns contain an immobilized primary or secondary amine functionality that is positively charged at mobile phase pHs below the pK_a of the amine (pH about 7.5 or less). Strong anion-exchange (SAX) columns contain a tertiary amine group that remains positively charged throughout the pH range. The WAX and SAX phases, therefore, are designed to retain anionic drugs (see section 4). Weak cation-exchange (WCX) phases carry a negatively charged carboxylic acid residue at mobile phase pHs around 6 or more. Strong cation-exchange (SCX) phases bear a negatively charged sulfonate group essentially throughout the pH range. Consequently, WCX and SCX phases are capable of retaining basic drugs (see section 4).

In summary, phase selection is primarily empirical. Quantitative structure–retention relationships (QSRR) studies have progressed in identifying at least one factor or descriptor responsible for a given reversed-phase HPLC separation, such as partition coefficient,[33] electronic characteristic,[34] solute bulkiness[35–37] and shape.[38] Yet many more descriptors may be involved in the final separation result. In one QSRR study, Kaliszan and Osmialowski[39] identified 16 structural descriptors in addition to some polar descriptors. An excellent review of QSRR application to reversed-phase HPLC is that authored by Kaliszan.[36]

Retention indices are used as indicators for choosing GC phases for classes of mixtures. For example, benzene serves as an indicator where aromatics or saturated hydrocarbons may elute using a particular GC phase. Similarly, butanol can be used as an indicator for where polar alcohols and aldehydes may elute. Coated GC phases may impart strong dipole and hydrogen bonding characteristics, such as the polyethyleneglycol

100% dimethylpolysiloxane

Polarity: nonpolar
Uses: solvents, petroleum products, pharmaceutical samples, waxes

5% diphenyl – 95% dimethylpolysiloxane

Polarity: nonpolar
Uses: flavors, environmental samples, aromatic hydrocarbons

6% cyanopropylphenyl
94% dimethylpolysiloxane

Polarity: slightly polar
Uses: volatile compounds, insecticides, residue solvents in pharmaceutical products

20% diphenyl – 80% dimethylpolysiloxane

Polarity: slightly polar
Uses: volatile compounds, alcohols

35% diphenyl – 65% dimethylpolysiloxane

Polarity: intermediately polar
Uses: pesticides, Aroclors, amines, nitrogen-containing herbicides

14% cyanopropylphenyl
86% dimethylpolysiloxane

Polarity: intermediately polar
Uses: pesticides, Aroclors, alcohols oxygenates

50% phenyl – 50% methylpolysiloxane

Polarity: intermediately polar
Uses: triglycerides, phthalate esters, steroids, phenols

65% diphenyl – 35% dimethylpolysiloxane

Polarity: intermediately polar
Uses: triglycerides, rosin acids, free fatty acids

trifluoropropylmethylpolysiloxane

Polarity: selective for lone pair electrons
Uses: environmental samples, solvents, Freons, drugs, ketones, alcohols

50% cyanopropylphenyl
50% phenylmethylpolysiloxane

Polarity: polar
Uses: FAMEs, carbohydrates

Carbowax@ PEG

Polarity: polar
Uses: FAMEs, flavors, acids, amines, solvents, xylene isomers

90% biscyanopropyl
10% cyanopropylphenylpolysiloxane

Polarity: very polar
Uses: FAMEs, *cis*/*trans* & dioxin isomers, rosin acids

phase attraction for low-molecular-weight alcohols. This adds a powerful resolving mode for mixtures that would otherwise elute based solely on their relative boiling points, which may be too similar to resolve. In general, polar phases retain polar solutes longer than do nonpolar phases.

3 CHEMISTRY OF BONDED PHASES

3.1 Gas Chromatography Coatings

Most GC phases are constructed by coating a static or dynamic layer of polymerizable silica-containing reagent(s) on the inside wall of a tube and then polymerizing it in place by heat or other processes. Film thickness can be controlled by the original reagent concentration. The reagent may contain a variety of functional groups, each contributing a unique quality to the separation process. Figure 5 shows a few marketed phases.

3.2 Modified Silica Phases

The silica particle surface may contain chemical diversity including siloxanes, geminal silanols, vicinal silanols, isolated silanols, and metal contaminants (Figure 6). A surface chemistry variation between brands is one of the primary reasons why no two C_{18} packings chromatographically behave the same. Geminal and isolated silanols are thought to be the most active silanols in causing undesirable peak tailing. Metal contaminants, such as sodium, magnesium and iron, also play a role in activating silanols. Vicinal silanols, hypothetically, are indicative of a more homogeneous surface, and are less active.

Active silanols may actually improve peak shape for acidic solutes compared to a nonactive packing.[40] These older ''type A'', active silicas are not suitable for basic or zwitterionic compounds. Newer, ''type B'', pure silica packings give superior peak shape for basic and zwitterionic solutes, and perform well for acids as well. Reviews covering the effect of silanols on basic compounds were composed by Nawrocki[41] and Cox.[42]

Traditional bonding chemistry involves covalently bonding a monofunctional, difunctional or trifunctional chlorosilane reagent to a surface silanol group in the presence of a tertiary amine proton scavenger, as shown in Scheme 2. Alkoxysilanes, such as trimethoxysilyl-, triethoxysilyl-, dimethylmethoxysilyl-, etc. may also be used and do not require a proton scavenger. The order of reactivity of silyl electrophiles is: SiCl > SiOMe > SiOEt. Presence of water in the bonding of di- or trifunctional reagents results in polymerization

Figure 6 Surface chemistry of silica particles.

Scheme 2 Traditional bonding chemistry on the silica surface.

of the reagent that may or may not covalently bond to silica silanols. Unbonded polymerized reagent may be difficult to wash out and could appear as bleed under certain mobile-phase conditions. The degree of polymer character of phases may be measured by a National Institute of Standards and Technology (NIST) test mix developed by Sander and Wise.[43] The mix is designated as standard reference material (SRM) 869. It contains three polycyclic aromatic hydrocarbons (PAHs): benzo[*a*]pyrene **(3)** (BaP) [50-32-8], 1,2-3,4-5,6-7,8-tetrabenzonaphthalene **(4)** (TBN) [34478-91-6]

(3)

(4)

(5)

and phenanthro[3,4-*c*]phenanthrene **(5)** (PhPh) [87-83-7]. Level of polymeric C_{18} bonded phase is measured based on the resulting selectivity and elution order of the PAH components in the SRM 869 mix run on the phase in question.

An end-capping step most often is performed following bonding, to reduce the number of active surface silanols further. The end-capping reagent, being smaller than the bonding reagent, bonds to silanols not accessible to the bonding reagent. Examples of end-capping reagents include trimethylchlorosilane [75-77-4] and hexamethyldisilazane [999-97-3].

Ludwig et al.[26] concluded that bonded-phase ligand density might play a role in hydrolytic stability of the bonded phase. Maximum ligand density or coverage is obtained by using excess bonding reagent and good synthetic technique. Moisture can hydrolyze the reactive bonding reagent and/or polymerize the precursor. Higher coverage also assists in deactivating active silanols. Larger pore size particles (e.g. 200–500 Å) may be more available to bonding reagents than 60–100-Å pore size particles, and may display superior base deactivation due to higher coverage. Larger pores are also preferred for separation of larger molecules such as proteins. Bonded phases with smaller pore sizes have greater surface area, higher percent carbon and longer retention.

3.3 Nonsilica High-performance Liquid Chromatography Phases

Polymeric and other nonsilica HPLC packings avoid active silanols altogether. State-of-the-art polymer particle and pore sizes are controlled with desirable narrow distribution. The pH stability is improved over silica-based packings as shown in Table 3. Polymeric columns still suffer in that they have lower efficiencies than silica-based columns. Polymers also tend to shrink and swell in certain solvents and are not as rigid as silica. For years, researchers have tried to overcome these shortcomings. Progress has been made, but the advantage remains with silica. Silica phases contain at least 10 000 plates m^{-1} more efficiency than the best polymeric phases in well-packed columns. Polymer phases still shrink and swell to some degree, even with high cross-linking. The major utilities of polymeric phases have taken foundation in applications requiring extreme pH conditions, and in ion exchange, size exclusion and biomolecule separations.

Porous glassy carbon (PGC) phases, such as the commercial product called Hypercarb®, can be run at any pH. The solid support is sp^2-hybridized, 100% carbon, formed at high temperatures, with a morphology described as being interwoven ribbon-like strands.[44] Figure 7 depicts how the material is believed to exist as a chromatography medium.

The flat surface of the ribbons acts as the location for certain adsorption processes of the solute. Positional isomers of derivatized phenyl groups, for example, are well discriminated by this adsorption mode of separation.[44] Molecules capable of more contact points with the PGC surface are retained longer than compounds with few contact points as pictured in Figure 8. The *o*-xylene isomer has four contact points on the PGC surface and is retained the longest. The second longest retained isomer is the *p*-xylene isomer which has four contact points temporarily on one side (a, b) of the molecule, but that can flip to the other side (c, d). Therefore, there may be times when it has just two points of contact as opposed to constantly having four contact points, as in the case of the ortho isomer. Finally, the meta isomer has just three points of contact with the PGC surface, and elutes first. This elution order is opposite to that seen on conventional C_{18} phases.

Stereoisomers are also good candidates for PGC phases as outlined by Karlsson and Pettersson,[45] where the flat surface aids in the ''three point attachment'' model first introduced by Dalgleisch.[46] The discriminating PGC phase was used by Azzoui et al.[33] to analyze

Table 3 Characteristics of some commercially available polymeric HPLC phases

Packing range	Manufacturer	Type	Pore size (Å)	Particle size (μm)	pH
PLP-1	Hamilton®	PS/DVB	75	5, 10	1–13
TSK Octadecyl-NPR	Toso-Haas®	PMM	Nonporous	2.5	2–12
Jordi® Gel DVB	Jordi®	DVB	100, 500, 10^3	5	1–14
ODP-50	Asahipak®	PVA	200	5, 9	2–13

Figure 8 Xylene isomer separation on a PGC phase.

benzodioxinic isomers that could not be separated by normal or reversed-phase HPLC or by GC.

Perhaps the greatest potential for PGC phases is in retaining very polar compounds. Solutes that do not retain on even the most retentive C_{18} phases should be tried on the PGC phase, which also operates on a reversed-phase mechanism. Solvent strength is very different for PGC than for C_{18} phases. Acetonitrile and methanol are strong solvents for C_{18} phases, but are relatively weak for PGC phases. The strength of solvents for PGC phases is solute dependent and not readily definable.[47]

PGC phases have also been prepared at low temperatures, where the degree of glassy carbon formation is controlled.[48] The degree of PGC formation dictates solute selectivity. The higher the process temperature used, the more the phase resembles Hypercarb®. Therefore, desired chromatographic activity can be ''tuned'' by controlling the temperature of PGC formation.

Low-temperature PGC phases have not been commercialized at the time of this writing.

Zirconia-based HPLC phases have recently entered the market under the tradename, Zirchrom®. The 3-μm zirconia solid support is extremely stable and is operable from pH 0 to 14.[49] Zirconia monomeric bonded phases appear to be significantly less stable than the corresponding silica monomeric phases. However, polymer, PGC and ionic coatings on the zirconia particles are available. Mass transfer appears to be slower on zirconia phases than on silica bonded phases, which is compensated for by running separations as high as 200 °C. The higher temperature conditions also reduce higher backpressures caused by the 3-μm particle by decreasing mobile phase viscosity.

Modified alumina phases have also been reported by Holland et al.[50] Although they are not robust throughout the entire pH range as are PGC and zirconia phases, they are stable from pH 2 to 13, which is an advantage over silica phases. Lingeman and Underberg[51] reviewed underivatized alumina which can be used both as an anion exchanger or a cation exchanger for the analysis of basic and acidic compounds, dependent on the pH of the mobile phase. Selectivity for acidic and neutral compounds was particularly good, although the retention mechanism was rather complex on alumina phases.

3.4 Direct Inject Columns

Considerable cost and sample preparation time savings can be realized using phases designed to handle the direct injection of serum and urine samples for pharmaceutical analysis. Early attempts involved automated column-switching techniques between two columns, which are still used today. The sample plasma or urine sample reaches the first column, where proteins and undesirable molecules are unretained and pass directly to waste. Meanwhile drugs to be analyzed are strongly retained and trapped on the first column. A valve is switched directing a stronger mobile phase to elute (usually by backflushing) the trapped drugs from the first column onto an analytical column and then to a detector. The first column (precolumn) is usually bonded with a diol-containing phase of some sort. This provides a ''protein friendly'' environment to which proteins will not stick. The second, analytical column must be sufficiently retentive to perform the drug separation under the strong mobile phase conditions needed to elute them off the precolumn. Yu and Westerlund[52] described such a system using an alkyl-diol precolumn and a C_{18} analytical column for direct plasma analysis of methotrexate [59-05-2]. Clarke and Robinson[53] reviewed several HPLC clean-up procedures, among which was the column-switching technique that gave high drug recovery rates of from 95% to 100%, and with low coefficients of variation. Other acclamations of the practice of this technique for the analysis of drugs in biological samples have been published.[54–56]

Phases were then developed with the concept of using one column that excludes proteins, but retains small molecules, especially drugs. Such a phase eliminates the need for the more complicated column-switching techniques. Pinkerton and Hagestam[57] were the first to introduce this notion, whereby small molecules were retained in the pores, which were bonded with a glycerylpropyl/glycine-L-phenylalanine-L-phenylalanine (GFF) phase. The outside surface was treated by carboxypeptidase A, which is too large to enter the pores. The external surface, after enzymatic treatment, contained glycerolpropyl/glycine chemistry, which occluded protein molecules from entering packing pores. Small solutes were retained in the pores by the GFF phase that survived enzyme treatment. The designation, internal surface reversed phase (ISRP) was given to describe the chemistry. Mohammad and Morrison[58] separated methylene violet biological stain in a DNA-containing sample matrix, on an ISRP GFF column. Perry[59] published an in-depth review of this packing. Shihabi[60] discussed some of the earlier pros and cons associated with ISRPs compared to other direct injection techniques of serums, which are still applicable today.

Other ISRP-like packings have been developed which are modifications of the original to varying degrees. Haginaka[61] summarized several of these phases including semipermeable surface (SPS), dual zone (DZ), shielded hydrophobic phase (SHP) and mixed functional phase (MFP). Collectively, they are known as restricted access phases.

4 MODES OF CHROMATOGRAPHIC SEPARATION

The most widely used modes of pharmaceutical analyses include reversed-phase, normal-phase and ion-exchange chromatography. Mechanisms describe, on the molecular level, how the separations occur.

Reversed-phase separations may take place by partitioning or adsorption mechanisms. Although there is still some debate, it is generally believed that C_{18} and similar hydrophobic phases retain solutes by their partitioning from the mobile phase into a solvated organic coating on the hydrocarbon stationary phase. Retention of solutes, therefore, is involved in a liquid:liquid partitioning process, as shown in Figure 9.

In contrast, PGC phases are thought to operate by an adsorption mode, which may explain the exceptional

Figure 9 (a) Partitioning, and (b) ion-exchange mechanisms. (From Restek Corporation with permission.)

selectivity these phases show for positional and stereoisomers. Figure 8 depicts a PGC hydrophobic surface that molecules interact with directly.

Normal-phase separations also occur either by partitioning or by adsorption. Prevalent thinking associates diol, amino and cyano bonded phases with the partitioning mechanism, whereas bare silica is postulated to act by adsorption.

Ion-exchange mechanisms include WAX, SAX, WCX and SCX, as discussed in section 2.5 and pictured in Figure 9. For ion exchange of acidic compounds, the mobile-phase pH should be at least one unit above the pK_a of the solute (pK_as of carboxylic acids are typically about 5) to deprotonate and ionize the acid. Basic solutes (pK_as of secondary and primary amines are ordinarily about 8 or 9, respectively) require a

mobile-phase pH of at least one unit lower than the pK_a of the analyte to protonate the species. A strong mobile-phase solvent is favored to reduce secondary modes of separation from transpiring. Elution of target solutes from the stationary phase ensues by mobile-phase additive ions displacing them from the ionic stationary phase. Gradients of increasing buffer concentration are typical, although isocratic ion-exchange separations are not uncommon. In practice, few separations are purely ion exchange, but also contain, for example, some secondary partitioning.

5 PHASE SELECTION BY ANALYTE FUNCTIONAL GROUP TYPE

5.1 Acids

Low-molecular-weight or polar acids are difficult to retain by reversed-phase columns. Retention of acids increases, while bases decrease, with lower pH mobile phases. Correspondingly, acids are less soluble and bases are more soluble in aqueous mobile phases at lower pH. Obviously, there are other factors that also contribute to reversed-phase retention. Most polar acid separations, therefore, are conducted at low pH to gain retention. However, peak broadening occurs when the analyte solubility in the acidic mobile phase becomes a significant issue.

To retain the most polar acid samples, earlier HPLC methods resorted to complex mobile phases with ion pairing agents on active, type A, silica C_{18} packings. For example, Honnegger et al.[62] separated ascorbic acid [50-81-7] and uric acid [69-93-2] from tissue extract using an active packing and a pH 3.5 mobile phase consisting of phosphate buffer, EDTA (ethylenediaminetetraacetic acid), and sodium octylsulfate. Methods of such enhanced complexity are difficult to reproduce.

Chang et al.[63] employed normal-phase amine and β-cyclodextrin (CD) columns to separate substituted benzoic acids under simpler mobile-phase conditions using acetic acid, isopropyl alcohol and methanol. Similarly, Mallet et al.[64] analyzed dihydroxyeicosatetraenoic acids by normal phase on bare silica using hexane, isopropanol, methanol and acetic acid as mobile phase. Separation by GC required derivatization to the corresponding *t*-butyldimethylsilyl or *t*-butylmethoxyphenylsilyl esters. However, normal-phase methods are generally not as robust as reversed-phase methods.

Acids separations may be performed on SAX or WAX columns. Under ion-exchange conditions, the mobile phase pH is adjusted to at least one unit higher than the pK_a of the solute to ionize the acid. As noted in section 2.5, WAX columns must also be used with a mobile-phase pH that is at least one unit below the pK_a of the bonded amine moiety. These two necessary conditions customarily place the working range of WAX columns at about pH 6–7.5. Silica-based SAX columns are also limited to approximately the same pH range, since higher pH mobile phases may hydrolyze the silica backbone. Xia and Gilmer[65] successfully retained the highly polar sialic acid [131-48-6] using a SAX column. Polymer-based SAX columns may be operated at higher pHs. Schmucker,[66] and Bulusu et al.[67] include reviews of some earlier ion-exchange separations of acids.

More recent developments in HPLC column technology seek to perform separations of polar acids by novel reversed-phase packings that provide more robust methods than nonreversed-phase modes of separation. Among these phases are the aforementioned IBD and high aqueous reversed-phase packings (see section 2.5). In another approach, Tischler and Cardellina[68] used a polybutyldiene-coated alumina phase to separate triterpene carboxylic acids without the need for any ion pairing, ion suppressing or buffering additives.

Acidic solutes of moderate to low polarity are relatively easy to separate on either Type A or Type B hydrocarbon phases. Abscisic acid [14375-45-2] and indol-3-ylacetic acid [87-51-4] contain sufficient hydrophobicity to be retained by conventional reversed-phase C_{18} packings.[69] Kwong[70] surveyed a variety of ways that the moderately polar acetylsalicylic acid (aspirin) [50-78-2] and its metabolites can be separated, including the use of C_{18} phases. More hydrophobic solutes, such as the fatty acid γ-linolenic acid [463-40-1], can be converted to esters for reversed-phase C_{18},[71,72] or for polyethyleneglycol phase GC[72] separation. However, derivatization often is not necessary for HPLC fatty acid separations.[73–76] The type of sample preparation for GC or LC (liquid chromatography) separations of pharmaceutically important organic acids depends largely on analytical objectives, as outlined by Liebich.[77] Mukherjee and Karnes[78] reviewed carboxylic acid derivatization reagents for HPLC, if the situation so warrants the additional effort required for this sample preparation.

Phenols should be recognized as weak acids owing to the acidic nature of the phenolic proton. Thomassin et al.[79] reported successful separations of several *p*-hydroxybenzoic esters and *p*-hydroxybenzoic acids on a standard C_{18} packing (also, see parabens in section 6.24). Cabaleiro and Cela[80] employed an active C_{18} column and protonated both stationary-phase silanols and the polyphenolic solutes with 1% acetic acid in the methanol and acetonitrile mobile-phase gradients. Polyphenolic acid retention on a PGC is dependent on the aromatic ring substitution, as documented by Vazquez et al.[81]

HPLC and GC separations of bile acids are summarized by Scalia.[82]

5.2 Bases

Tailing of basic solutes on silica HPLC packings is commonly rationalized by analyte interaction with surface silanols (see section 3.2). Tetraalkyl ammonium ions, sometimes referred to as ion suppressing agents, mask active surface silanols, greatly improving peak shape for basic solutes. Such additives were particularly important in earlier separation techniques before type B silica packings became available.[83] Even with type B silica phases, improvements may be seen with ion suppressing agents.[84] Peak shape can also be improved by using acidic mobile phases that protonate silica siloxides. This may be undesirable for polar basic compounds since lower pH generally elutes bases faster than when the pH is neutral. Good base deactivated phases offer a clear advantage in such situations.

Normal-phase separations of basic compounds on bare silica and alumina were reviewed by Lingeman and Underberg.[85] Additional base solute separations are listed in section 6.

5.3 Acid/Base Mixtures

Mobile-phase conditions optimized for acids may not be favorable for bases and vice versa. Conventional packings do not handle a mixture of both kinds very successfully. Problems with retention and peak shape of one or both solute types are commonplace, even with all but the most base deactivated, type B phases. On C_{18} phases, bases decrease in retention and sharpen in peak shape, while acids decrease in retention and broaden in peak shape with decreasing pH (for example, see results published by Das-Gupa and Mathew[86]). One of the advantages of IBD phases is that they show excellent peak shape for acid/base mixtures for a wide pH range and have complementary selectivity to C_{18} phases.[32] However, highly base deactivated C_{18} phases are more predictive of retention characteristics and separate most mixtures encountered by analysts. Mutton[87] claimed that one phase type successfully separated 95% of 1250 acid and base pharmaceutical candidates synthesized in the preceding year.

For methods development of acids and bases on reversed-phase columns, Zhu et al.[88] recommend starting by varying the gradient steepness and beginning at low pH. If the variation of these two parameters does not achieve the desired selectivity, the effect of temperature should then be explored. Snyder[89] estimated relative contributions of temperature, solvent strength,[90] column type and solvent type towards selectivity and weighed these factors against the ease of operation in changing them. Varying percent organic in the mobile phase, temperature and solvent type (methanol or acetonitrile) was advocated first. If ineffectual, solvent type (methanol, acetonitrile or tetrahydrofuran), column type, pH and/or ion pair reagent concentration deviations should be tried next.

5.4 Zwitterions

Because they contain both acid and base functionality on the same molecule, zwitterionic solutes can sometimes pose challenging problems in obtaining good peak shape and retention. As might be expected, IBD phases have excellent peak shape for zwitterionic compounds, in addition to acids and bases.[32]

Stationary phases of multimode separation ability have been prepared by immobilizing a zwitterionic molecule onto silica particles. Yu et al.[91,92] bonded glutamic acid to silica and were able to separate acids and bases simultaneously, including nucleosides. Chou and Yang[93] simultaneously ran acids, bases and amino acids on an immobilized zwitterionic stationary phase. Yang et al.[94] invoked a similar ''like-retains-like'' strategy in preparing two other zwitterionic stationary phases.

5.5 Polar Compounds

Retention of polar ionic solutes is discussed in sections 5.1 through 5.4. As with those solutes, methods development of nonionic polar analytes is best performed under reversed-phase conditions, if possible. Newer high aqueous reversed-phase columns and IBD phases (section 2.5) are ideal for extra retention accrual.

5.6 Halogenated Compounds

HPLC stationary phases have been developed that provide exceptional selectivity for pharmaceutical compounds containing halogen atoms. Perhaps conceived by a ''like-retains-like'' strategy, these stationary phases contain halogenated groups themselves. The most popular halogen for this purpose is the fluorine atom, possibly because of its strong electronegative nature. One of the more common commercially available fluorinated packings is known as Fluofix®, a partially fluorinated branched hydrocarbon stationary phase (Figure 10).

Maisch[95] depicted several advantages of this phase. The fluorinated packing separated fluorinated adrenocortical hormones and the epimers 3-β-panaxadiol [19666-76-3] and 3-α-panaxadiol, which could not be resolved on traditional C_{18} phases. It appears to show good selectivity for positional and *cis/trans* isomers as well. Jinno and

Figure 10 Fluorinated Fluofix® stationary phase.

Nakamura[96] attributed the special selectivity of polar solutes to the larger polarity of the fluorinated phase compared to C_{18} phases. Aboul-Enein and Serignese[97] accomplished the separation of taxol A [33069-62-4] and five of its derivatives using a Fluofix® column.

Taxol and related compounds have also been separated on a pentafluorophenyl (PFP) phase.[98] Another PFP phase, a heptadecafluorodecyl phase and a 3-(heptafluoroisopropoxy)propyldimethylsilane phase exhibited marked retention differences compared to C_{18} phases, affected by different solute functional groups.[99]

Krafft et al.[100] credited the greater transfer energies of the CF_2 over the CH_2 groups with achieving longer retention and better separation of a series of perfluoroalkylated compounds on two perfluoroalkylamino stationary phases compared to a C_{18} phase. Rectilinear plots of capacity factor versus number of carbon atoms were obtained. Also, utility was found for fluorinated stationary phases in the analysis of fluorinated surfactants,[100] flavonoids and fluorinated phenols,[101] and for high recovery rates of proteins.[102] Similar to silica-based fluorinated bonded phases, Hirayama et al.[103] discovered that a perfluoroalkyl acrylate phase provided more efficient separation of fluorine-containing compounds than a C_{18} packing. It is noteworthy that one nonfluorinated phase, poly(vinyl *p*-*t*-butylbenzoate), also showed preferential retention of halogenated solutes compared to C_{18} silica, polystyrene/divinylbenzene and poly(methyl methacrylate–ethyl dimethacrylate) phases.[104]

Dhanesar and Poole[105] compared GC fluorinated phases to nonfluorinated phases in separating some halogenated solutes. Organic compound retention was determined to be about 2–6 times less on the fluorinated versus nonfluorinated stationary phases of similar polarity.

Fluorinated phases are not the only phases suitable for halogenated compound separations. Conventional C_{18} packings often are sufficient. For example, 5-fluoro-2′-deoxycytidine [10356-76-0] and 5-trifluoromethyl-2′-deoxycytidine [66384-66-5] were detected on a C_{18} phase by Briggle et al.[106] Leone and Collins[107] employed simple isocratic mobile phases in separating nine simple perhalogenated compounds on C_{18} phases. Interpolation curves of log mass distribution ratios versus number of solute chlorine atoms accurately predicted observed retention times.[108] Yamaguchi and Hanai[109] compared high versus low carbon load and end-capped versus nonend-capped C_{18} phases for solutes including some halogenated phenols. They concluded that the low carbon load, nonend-capped C_{18} phases gave superior selectivity, but suffered from short column lifetime. De Vries and Rekker[110] separated halogen-substituted aromatic compounds on bare silica and alumina packings under normal-phase conditions. Retention was significantly affected by the substitution pattern of the aromatic solutes and by the bulk and mobility of the mobile-phase molecules.

Documented GC analysis of halogenated pharmaceuticals, as with nonhalogenated pharmaceuticals, is far less prevalent in recent literature than is HPLC analysis publications. GC analysis finds usefulness with more volatile compounds in pharmaceutical analysis, such as drug headspace analysis,[111] urinary halogenated hydrocarbon degradation products in drugs of abuse screening,[112] and analysis of the highly volatile anesthetic, halothane.[113] Some organohalogen drugs in legal medicine analysis by GC/MS were summarized by Suzuki et al.[114]

5.7 Chiral Compounds

Drug candidates containing a chiral center(s) present a unique challenge to the analytical chemist. Racemic compounds, differing only by the arrangement of atoms in space, represent the most challenging of all mixtures to separate. Isolation of the individual enantiomers is very important for evaluation of their respective biological activity and toxicity, which may be quite different. For example, Silber et al.[115] reported that the (*S*)-isomer of propranolol is 100 times more potent as a β-blocker than the (*R*)-isomer. In extreme cases, racemic drugs may be considered to be only 50% pure owing to the presence of the inactive enantiomer. Krstulovic[116] summarized some complex activity, toxicity and pharmacokinetic scenarios possible with racemic drugs. Although the US FDA does not currently require it, potential biological activity differences associated with stereoisomers make it prudent for pharmaceutical companies to determine each enantiomer's individual activity and toxicity. Chromatographic resolution of enantiomers has rapidly expanded as a result. This work mainly involves three processes for chromatographic separation of racemic mixtures, in using chiral stationary phases (CSPs), chiral mobile phase additives (CMPAs) and a CSP and CMPA simultaneously.

Choice of CSPs largely remains empirical at the time of this writing. The best approach is to choose a column that is known to separate racemates of similar structure, and/or meets the general requirements outlined in the literature for successful chiral recognition of the CSP for the solute. Trace analysis of enantiomers may benefit from having the option to choose between a (*R*)-CSP and the corresponding (*S*)-CSP. It is generally desirable to have the minor enantiomer elute before the major enantiomer, so that the latter does not tail into the former, in closely eluting peaks. If, for example, a (*R*)-CSP elutes the minor enantiomer last, then switching to the opposite (*S*)-CSP will reverse the elution order, as desired, without changing any other chromatographic conditions.

In chiral separations where mixtures contain overlapping metabolic peaks, two or more columns with different selectivities may be used to effect separation. For example, Fried and Wainer[117] used a diol silica precolumn to perform an achiral separation of verapamil [52-53-9]/verapamil metabolites and norverapamil [67812-42-4]/norverapamil metabolites, which was then coupled to a chiral column for enantiomer separation. Without the initial achiral separation, overlap of nonenantiomeric peaks was problematic. Ducharme et al.[118] commented that chiral methods validation ideally should be conducted on each enantiomer and the racemate, in order to document the amount of interference between the enantiomers, if any. Figure 11 exemplifies one possible interference, where Fujima et al.[119] recorded racemization of lorazepam [846-49-1] at 25 °C. The baseline rise between eluting enantiomer peaks is indicative of racemization and the method should be modified to avoid this problem.

Chromatographic separations of enantiomers was initiated in 1952 by Dalgleish[46] in his ''three point interaction'' model depicting the stereogeometric interaction of racemic solutes with a single-enantiomer stationary phase. (Biochemists may readily associate the analogy

Figure 11 Temperature-dependent racemization of lorazepam enantiomers on an ovomucoid (OVM) chiral column. Column temperature: 7 °C (a), 10 °C (b), 15 °C (c) and 25 °C (d). (Reprinted from H. Fujima et al.[119] *J. Liq. Chromatogr.*, **16**(4), 879–891, 1993, by courtesy of Marcel Dekker, Inc.)

of this model to the Ogsten, ''three point landing'' model[120] diagramming stereochemical interactions of active biomolecules with enzymes/proteins). The model involves interactions between three groups bonded to the chiral center on the analyte with three groups on the CSP, as displayed in Figure 12. Solute enantiomer a has a more favorable ''fit'' to the stationary phase regarding attractive interactions than does solute enantiomer b. Therefore, a is retained longer than b. It is important to note that not all three interactions need to be attractive interactions. Steric hindrance and charge:charge repulsions may also contribute.

Some of the earliest commercially available chiral HPLC phases were the so-called ''brush type'' or ''pirkle'' phases, the latter of which was named after the inventor. One of the three points of interaction which is a characteristic of pirkle phases is $\pi : \pi$ attraction. The CSP dinitrobenzoylphenylglycine (DNBPG) molecule in Figure 13 has electron-withdrawing groups on the aromatic ring that produce an electron-deficient or π-acidic phenyl ring. This CSP is designed for solutes containing an electron-rich or π-basic aromatic ring, which acts as one of the three interactions for chiral discrimination. Solutes that are successfully separated on this phase often, but not always, contain an amide group on the ring, similar to the CSP. This structural ''requirement'' can be met for primary and secondary amine analytes by derivatization with, for example, benzoyl chloride or naphthoyl chloride.

For π-acid solutes, CSPs containing π-base phases are commercially available, such as the naphthylethylurea CSP displayed in Figure 14. With this phase, a suitable

Figure 12 Dalgleish three point interaction model.

Figure 13 π-Acidic CSP. ⋆ CSP chiral center.

Figure 14 π-Basic CSP. ⋆ CSP chiral center.

derivatization reagent for primary and secondary amines might be 3,5-dinitrobenzoylchloride.

Many commercial brush-type phases have been developed over the years, with varying degrees of success. In general, they do not demonstrate a broad range of applicability without solute derivatization.

The spectrum of underivatized compounds capable of being separated on one particular phase increased with the advent of CD phases. Commercial CD phases are currently available for both HPLC and GC separations. The three most prominent phases, α-, β-, and γ-CD, contain 6, 7, and 8 glucopyranose rings, respectively, hooked by 1,4-linkages as shown in Figure 15. The respective cavity sizes are 4.5 Å, 6 Å and 8 Å in diameter.

Retention may occur by either inclusion of a hydrophobic portion of the analyte into the cavity or by ''capping'' the top of the CD cavity.[121] Hydroxy groups at the mouth of the CD molecule are available for hydrogen bonding as part of the discrimination process, which is especially important for enantiomers, and also to some extent in separations of structural and geometric isomers. Commercial permethylated CD columns are also available, and appear to separate an even broader range of racemates than unmodified CD phases. They should be tried first, unless the analyte contains hydroxy functionality, which underivatized CD phases may better recognize through hydrogen bonding.

Figure 15 CD structures. α-CD ($n = 1$), β-CD ($n = 2$) and γ-CD ($n = 3$).

Immobilized proteins (affinity phases) are fairly versatile in separating a wide range of underivatized chiral solutes. They take advantage of the natural chiral recognition processes of biological systems. Commercial columns include bovine serum albumin (BSA), human serum albumin (HSA), OVM, α_1-glycoprotein (AGP) and other phases. The proteins are usually covalently bonded to a 300-Å silica support, which contains a large enough pore size to incorporate the protein. Among the serum albumin phases, it is interesting to note that, although there is a high homology between the various sources (bovine, human, sheep, pig, etc.), Tittelbach and Gilpin[122] found that small differences in the amino acid sequence can have a pronounced effect on solute selectivity. Lower column temperatures often increase resolution, presumably by freezing protein conformation, thereby improving enantiomer recognition. Some drawbacks of protein phases include slower mass transfer characteristics causing peak broadening and mobile-phase restrictions that are recommended by column manufacturers to avoid denaturing the protein.

Derivatized cellulose CSPs provide a broad range of separations as summarized by Aboul-Enein and Islam.[123] With the exception of triacetyl and tribenzoylcellulose, derivatized cellulose phases are largely covered by patents owned by Daicel Chemical Industries Ltd., Tokyo, Japan.

Chiral ligand exchange chromatography (CLEC) was introduced by Davankov[124,125] in 1970. Amino acid racemates may be separated without derivatization, using the CLEC phase, which incorporates an immobilized single enantiomer amino acid. The amine and carboxylate functional groups complex with a metal ion, such as copper, which in turn complexes with the amino acid solutes. The solute enantiomer that forms the most stable complex is retained longer, giving rise to the separation process. Disadvantages of this technology include long equilibration times associated with the metal-containing complex mobile phase, and that the technology is not compatible with MS (mass spectrometry) detection.

Chiral crown ether phases embody cavities involved in the separation of racemic mixtures containing primary amines. Sousa et al.[126] first introduced these phases, which were latter modified for free amino acid racemate separations.[127] Secondary and tertiary amines do not separate on these phases, which limits their usefulness. However, Hilton and Armstrong[128] have successfully separated dipeptides.

Chiral imprinted gels are very specific for a targeted racemic mixture. A solute enantiomer is used as a template, bound in a cross-linked polymer. The template molecule is then removed by hydrolysis, leaving a cavity that retains the identical enantiomer or one with very similar structure.

Another application-specific chiral phase was developed for racemic barbiturates, hydantoins and glutarimides by Feibush et al.[129] The phase contains functionality strategically located to form triple hydrogen bonds with the solutes, similar to biochemical base pair formation.

A more recent development of CSP technology is the macrocyclic chiral phases published by Szczepaniak and Szymanski,[130] and then expanded upon by Armstrong et al.[131] Molecular cavities, reminiscent of crown ether and CD cavities, but larger and of different chemistry, are thought to be involved in the separation process. The number and types of racemate that are separable is reported to be greater than any other single chiral phase, although the reproducibility of the commercial phase may prove to be difficult to control. Among the most popular covalently bonded macrocyclic chiral phases are vancomycin [123409-00-7] for N-protected amino acids and drugs[131] including warfarin [81-81-2],[132] teicoplanin [61036-62-2] for protected amino acids[132] and underivatized amino acids, peptides, α-hydroxycarboxylic acids, cyclic amides and amines,[133] and ristocetin A [1404-55-3] for derivatized or underivatized primary and secondary amino acids and di- and tripeptides.[134]

CMPAs can be used in conjunction with a standard C_{18} or other reversed-phase column. Here, the recognition occurs by the complexing of the CMPA with each of the enantiomers. The complex formation results in two pseudodiastereomers, which nonchiral phases are capable of discriminating between.

Chiral separations can be predictably improved by using both a CSP and a structurally homologous CMPA in concert. Somewhat surprisingly, the beneficial CMPA (of opposite stereochemistry to the CSP) does not elute the less retained solute enantiomer from the column relatively faster than the other solute enantiomer, but rather performs a proposed stereoselective ''salting out'' process. The longer retained solute isomer, hypothetically, is forced to reside longer on the bonded phase by being salted out of the mobile phase. Therefore, enhanced CSP/CMPA enantiomer separations occur solely due to the more retained enantiomer, while the less retained enantiomer is not affected in a chiral recognition sense. Duff et al.[135] proposed a ''push/pull'' model to describe this process, as shown in Figure 16.

6 PHASE SELECTION BY ANALYTE CLASS

6.1 Adrenergic

Pharmaceutical separations of adrenergic β-blockers can be accomplished on ordinary C_{18} phases. Maguregui et al.[136] analyzed urinary alprenolol [13655-52-2],

Figure 16 Push/pull model for CSP/CMPA synergism. (Reproduced from K. Duff et al.[135] *Chiralty*, **5**, 201–206. Copyright 1993, with permission from Wiley-Liss, a subsidiary of John Wiley & Sons.)

atenolol [29122-68-7], metoprolol [37350-58-6], nadolol [42200-33-9], oxprenolol [6452-71-7] and timolol [26839-75-8] at the parts-per-billion level using a common C_{18} column and electrochemical detection. Pindolol [13528-86-9] in urine and plasma was determined by Ohta et al.[137] using a column-switching technique (see section 3.4), with the second column (the analytical column) being a C_{18} phase. It is important to note that lower wavelengths of about 230 nm should be used for many β-blockers in order to detect them by UV absorbance.

Chiral separations for racemic atenolol, bevantolol [59170-23-9], celiprolol [56980-93-9], metipranolol [22664-55-7], metoprolol, oxprenolol, pindolol, propranolol and sotalol [3930-20-9] were accomplished by Ceccato et al.[138] on an AGP phase (see section 5.7). Attempted chiral resolutions of 18 β-blockers were conducted on a newer generation pirkle phase and compared to separations on a cellulose phase (see section 5.7).[139] Toyo'oka et al.[140] obtained low levels of detection of ten racemic β-blockers by derivatization with a chiral fluorescent reagent, followed by HPLC analysis of the resulting diastereomers on a C_{18} phase.

Although they are not nearly as well documented in the literature, chiral β-blocker separations can also be directed by GC CD phases, as demonstrated in Figure 17.[141]

Figure 17 GC Separation of racemic ibuprofen. 30 m, 0.32-mm ID, 0.25 m Rt-βDEXsm, on column injection, concentration approximately 125 ng each enantiomer; oven temperature 175–200 °C at 2 °C min^{-1}, injection/det. temperature 200 °C/230 °C; carrier gas, helium at 60 cm s^{-1}; detector type, GC/FID; split ratio 13 : 1 using cup splitter sleeve. (From Restek Corporation with permission.)

6.2 Alkaloids

Isoquinoline [119-65-3] and other alkaloids are best separated by HPLC. The choice of separation mode

varies with the sample matrix type. For example, alkaloids in poppy extracts are preferably separated by ion pair chromatography on an aminopropyl phase, while those in biological liquids may primarily be separated by ion-exchange or reversed-phase chromatography.[142] Metabolites of alkaloids are separable from their parent compounds by HPLC.[143] Review articles on alkaloid analyses have been published by Kabulov et al.,[144] Papadoyannis[145] and Valka.[146]

6.3 Amino Acids

Earlier amino acid separations (also see section 5.4) were run by methods using dedicated cation-exchange columns such as outlined by Walker and Mills.[147] Post-column derivatization with, for instance, ninhydrin[148] was common to improve detection. A large variety of precolumn derivatization reagents gradually emerged for the analysis of amino acids. Review articles can be found for *o*-phthaldialdehyde,[149] dabsyl chloride,[150] phenylisothiocyanate[151] and fluoren-9-ylmethyl chloroformate.[152] Selective derivatization reagents, for example benzoin for arginine [74-79-3] and glyoxal for tryptophan [54-12-6], are reviewed by Cui et al.[153] The derivatized amino acids can conveniently be run on reversed-phase columns.

6.4 Antibacterial/Antifungal

Watanabe et al.[154] analyzed methylated oryzalides and oryzalic acid rice extracts containing antibacterial activity by GC/MS. The derivatized terpenes were separated on a methyl silicon GC column and detected by selective ion monitoring. Fluconazole [86386-73-4] in human plasma was analyzed by Beijnen et al.[155] on a HP-1 GC phase. Other GC methods require modification of the analyte, such as derivatization of plasma canellal [66550-09-2] with bis(trimethylsilyl)trifluoroacetamide and subsequent GC/MS analysis on a DB-1 column.[156] Saponified steroidal lanosterol [79-63-0] isomers were derivatized by Howell and Mallet[157] to the corresponding trimethylsilyl or *t*-butyldimethylsilyl ethers before isolation on a SE-30 column.

Antifungal agents are more prevalently separated on reversed-phase HPLC columns. A cyclic hexapeptide antifungal agent was separated from plasma or urine on a conventional C_8 column by Schwartz et al.[158] Zornes and Stratford[159] used the same type of C_8 phase to assay a lipopeptide antifungal agent in plasma. Another reversed-phase column, this time a C_{18} phase, was employed by Chung and Paik[160] in discovering the presence of the antifungal active alkaloid ingredient, berberine [2086-83-1], in Japanese quince. Other examples of antifungal separations on conventional reversed-phase HPLC columns include fluconazole,[161,162] nystatin [1400-61-9],[163] heptaenes,[164] the nonapeptides, herbicolin A [74188-23-1] and B [74188-24-2],[165] and bromosalicylchloranilide [3679-64-9].[166] Both reversed-phase and normal-phase columns were used by Bergeron et al.[167] in isolating antifungal polyphenols from milkwort plants. Albet et al.[168] used a cyano phase to analyze the imidazole antifungal, sertaconazole nitrate [99592-39-9], which provided excellent separation of the target from impurities. Stopher and Gage[169] used a SEC column to elute directly injected plasma proteins, while trapping voriconazole on a C_{18} guard column. HPLC separation was then conducted on a 250 × 4.6-mm C_{18} phase. A less conventional β-CD column was successfully employed by Kim and Lin[170] in analyzing a triazole drug in human plasma. Reviews of antifungal analyses have been published by Woestenborghs and Heykants,[171] Ristuccia[172] and Warnock et al.[173]

6.5 Anti-inflammatory

Anti-inflammatory (also see section 6.30) drug analyses are largely accomplished by reversed-phase chromatography. Review articles covering methods through the 1980s include those written by Van Overbeke et al.,[174] Bojarski,[175] McElnay[176] and Wilson.[177] The former two referrals specifically cover enantiomer separations. Ho and Chen[178] have summarized some analytical methods.

6.6 Antipsychotic

A novel basic antipsychotic agent (also see section 6.9) and its N-oxide metabolites in plasma were analyzed using a C_{18} phase and an ion pairing reagent.[179] Reversed-phase HPLC has also been suggested as a possible diagnostic tool for postpartum psychosis.[180] Psychotic subjects showed a different pattern of compounds in their cerebral spinal fluid in comparison to normal subjects.

6.7 Anthracene Derivatives

Van den Berg and Labadie[181] separated several structurally similar cathartic (purgative) agents on an active C_{18} phase. Excellent separation was obtained for the anthracene-like compounds chrysophanol [481-74-3], physcion [521-61-9], emodin [518-82-1], aloe emodin [481-72-1] and rhein [478-43-3]. A custom copper(II)phthalocyanine sulfonylaminopropyl silica phase was found to separate electron-rich anthracene and other compounds by Saito et al.[182] Anthracene moieties are also used as fluorophore derivatization agents, such as that described by Goto et al.[183] for 3-oxo-bile acids.

6.8 Barbiturates

(See section 6.17.)

6.9 Benzazepines/Benzodiazepines

Benzazepines and benzodiazepines are sufficiently lipophilic that they are often analyzed on a C_8[184–189] or phenyl[190] phase instead of a C_{18} phase. Still, C_{18} phases dominate in the literature.[191–210] Bare silica, cyano and amino normal-phase columns have also been used for several benzodiazepines containing hydrogen bond donor or acceptor groups.[211] Radwanska et al.[212] studied dibenzazepines' interaction with melanin by analyzing the drugs on a melanin-bound aminopropyl silica phase and hydrophobicities were determined on an immobilized artificial membrane (IAM) phase. The chemistry of the IAM phase is designed to mimic cell membranes, as outlined by Alvarez et al.[213]

Benzazepines and benzodiazepines may exist in two twist boat conformational forms, a cup-shaped *anti* form and an extended *syn* form.[214] These ''frozen'' conformations may be visualized by proton NMR, and conformer adsorption coalescence can be obtained by heating the NMR sample. It is interesting to note that Fellegvari et al.[215] documented the ability to study benzodiazepine conformation interconversions, also by HPLC.

Benzodiazepine positional isomers were separated by Jin et al.[216] on a C_{18} phase. Franzelius and Besserer[217] separated diastereomeric isomers using a β-CD column (see section 5.7). Enantiomeric separations were accomplished on cellulose CSPs (see section 5.7) without the need for derivatization.[218] Some benzodiazepine enantiomers, specifically related to the 3-chiral position, were separated by Nishikawa et al.[219] and Fitos et al.[220] Separations related to the 5-chiral position are also reported.[220,221]

This class of analytes is somewhat unique among the pharmaceuticals in that, in addition to the many HPLC methods, there are also numerous GC separations appearing in the literature. Most methods are performed by GC/MS and use a variety of columns including SPB-5,[222] DB-1,[223] DB-5[224] and a 5% phenylmethylsilicone phase.[225] Methods for urinary samples,[223,224,226–231] blood/plasma samples,[222,225,232–238] and tissue samples are reported.[239] Noninvasive analyses have been gaining emphasis and forensic science has made advancements in technology, reflected by the development of analyses of benzodiazepine in human hair[240–242] and sweat.[243]

6.10 β-Blockers

(See section 6.1.)

6.11 Blood Volatiles

Typically, determination of blood volatiles is conducted by GC/MS using headspace analysis. Blood level ethanol [64-17-5] and other volatiles in drunk drivers were measured by Schuberth[244] on a DB-WAX phase coated with polyethyleneglycol. Isovaleraldehyde [590-86-3] in plasma from hepatic encephalopathy subjects was separated on a polyoxyethylene glycol phase by Al Mardini et al.[245] Dunn et al.[246] examined *N*-nitrosamines in blood using a carbowax column. Other volatiles analyzed in blood include organic pollutants,[247–254] halocarbons,[255–257] anesthetics,[258–261] multiple drugs taken by a suicide subject,[262] mercury [7439-97-6] (following ethylation derivatization),[263] blood cell membrane peroxidation residues,[264] solvent thinner[265] and EDTA[60-00-4] (following esterification).[266]

HPLC analysis of blood volatiles generally requires derivatization. For example, Vollmer et al.[267] derivatized ethylene glycol [107-21-1] with benzoyl chloride before HPLC separation on a C_{18} column. However, literature applications are largely of GC, not HPLC, methodology.

6.12 Cardiovascular

Cardiovascular agents containing basic moieties are best separated on type B silica reversed-phase packings. Nevertheless, many literature methods include type A reversed-phase separations. Using the more active type A silica requires ion-pairing and/or ion-suppressing reagents to be added to the mobile phase. Bonazzi et al.[268] used an active C_{18} phase to determine the angiotensin-converting enzyme (ACE) inhibitors, ramipril [87333-19-5], quinapril [85441-61-8], benazepril [86541-75-5], lisinopril [83915-83-7] and enalapril [75847-73-3]. Even with sodium heptanesulfonate mobile-phase additive, a low pH (2.5) was required to avoid peak splitting and band broadening. The more complex mobile phases were also needed for similar cardiovascular separations on type A packings.[269–272] Normal-phase bare silica columns have been used for cardiovascular separations, both with water[273] and without water[274] in the mobile phase. Review articles on the HPLC separation of eicosanoids[275] and on GC analysis of lipoprotein (a) [159577-00-1] and homocysteine [454-29-5] for risk factor studies of cardiovascular disorders[276] have been published.

Chiral separations of cardiovascular drugs include pindolol on an AGP affinity column,[277,278] and several brush-type phases were compared for a series of basic solutes.[279]

6.13 Catecholamines/Phenols

The HPLC analysis of catecholamines (also see section 6.24) has grown since the 1970s and is presently the major method of analysis. Cation-exchange columns are used under acidic conditions, where the amine functionality of the catecholamine is essentially completely

protonated. Newer type B reversed-phase columns often give excellent peak shape and selectivity and are a good first choice phase for methods development. The reader is referred to several review articles for HPLC separations.[20,280–283] Analysis by GC/MS is also popular and is reviewed in the literature.[284,285]

Phenolic compounds are weak acids and may be separated by anion-exchange columns as previously discussed (see section 5.1). Simple reversed-phase packings are a preferred alternative. Bosch et al.[286] documented a review of phenolic compound separations.

6.14 Cephalosporins/Penicillins

Cephalosporins/penicillins are relatively labile compounds, subject to acid and, especially, base hydrolysis. Care should be exercised in choosing a pH at least one unit away from the pK_a of the solute. Penicillins are generally strong organic acids, with pK_a values less than 3. Therefore, HPLC separations most often are run with a mobile phase pH in the range 4.5–7.5.[287] Active reversed-phase packings often show unacceptable peak tailing, chiefly at neutral pH mobile phases. Before type B packings became available, methods using active C_{18} and other reversed-phases resorted to ion-pairing or ion-suppressing mobile-phase additives.[288–291] A method for metronidazole [443-48-1] analysis by Venkateshwaran and Stewart,[292] demonstrates that a type B reversed phase can be used with simpler mobile phases (phosphate buffer and methanol in this case). The IBD phases (see section 2.5) are particularly valuable for analyzing this class of compound yielding excellent peak shape and selectivity even under neutral pH conditions.

Elevated temperatures accelerate decomposition. Because of the lack of thermal stability, GC methods for cephalosporins/penicillins are few.[293,294]

6.15 Cold Medicines

Cold medicine ingredients are relatively easily separated with good peak shape on type B silica reversed-phase packings. Caffeine [58-08-2] is often used in reversed-phase test mixes as a control for testing the level of base deactivation of packings. It maintains fairly sharp peak shape even with the more active phases, whereas other basic compounds may interact with the silanols so strongly that they do not elute.

6.16 Cyclosporins

The undecapeptide cyclosporin A [59865-13-3] is an immunosuppressant agent administered to organ transplant patients, which is slightly better than standard azathioprine and prednisone treatment. Whole-blood monitoring of cyclosporin A (as opposed to untrustworthy plasma analysis) is important in monitoring graft rejection which occurs below the 100 ng mL^{-1} level.[295] HPLC monitoring has been shown to be more accurate than radioimmunoassay which gave spuriously high results in multiple doses.[295] Bowers and Mathews[296] suggested that a broad unsymmetrical HPLC peak shape associated with the molecule is due to the various tertiary isomers in which the compound exists. Moyer et al.[297] used the minimum retention of a C_1 column and elevated temperature to reduce the apparent bandspreading for a more aesthetic chromatogram. Nishikawa et al.[298] latter found that cyclosporins A, C [59787-61-0] and D [63775-96-2] undergo interconversions between two molecular forms, whose chromatographic peak shapes are affected by both temperature and flow rate. Other researchers have used more retentive phases to discern structural cyclosporin[299,300] and cyclosporin metabolite[301,302] differences, particularly with LC/MS analyses.[303] Nazir et al.[304] used a highly selective PGC (see section 3.3) to separate two cyclosporins that differ in structure by just one methylene group.

6.17 Drugs of Abuse

Reviews of methods of analysis of illicit drugs (also see sections 6.9, 6.20, 6.27 and 6.32) include drug screening in law enforcement,[305] forensic and biomedical sciences,[306,307] Olympic[308] and Pan American Games[309] sports and the workplace.[310,311] GC/MS methods are the most prevalent in the literature and are required in the *Mandatory Guidelines for Federal Workplace Drug Testing Programs*.[311] A dated, yet thorough review of GC/MS methods (which include the GC phases employed) covering publications from 1981 to 1991 was documented by Maurer.[312] Published HPLC methods are also numerous and include review articles by Shihabi and McCormick[313] and Turcant and Kohn.[314]

6.18 Enkephalins/Endorphins

Enkephalins are either of two pentapeptides having the formula, H_2N-Tyr-Gly-Gly-Phe-X, where X is leucine or methionine. Endorphins are any of three peptides: the 30 amino acid C-terminal of β-lipotropin (β-endorphin) [19666-76-3], the 16 residues of the N-terminal of β-endorphin (α-endorphin)[59004-96-5], or the 17 residues of the N-terminal of β-endorphin (γ-endorphin) [61512-77-4]. Both enkephalins and endorphins bind to opioid receptors and are neurotransmitters that play a role in pain perception, among other biochemical functions.

HPLC is clearly the method of choice for determination of these peptides. In particular, several LC/MS methods have been developed that provide powerful analytical data.[315–318] Common C_{18} columns are often used in

these analyses. Several reversed phases were compared by Hearn and Aguilar[319] for retention and band broadening of the peptides. Likewise, Purcell et al.,[320] compared a C_4 and C_{18} phase for retention and bandwidth and studied conformational changes of the solutes during chromatographic migration. Conformational changes of β-endorphin on a C_{18} phase are believed to occur depending on mobile-phase organic content, flow rate and temperature.[321,322]

6.19 Glycosides

Glycosides (also see section 6.20) are compounds that contain a carbohydrate molecule, particularly from natural products in plants. Cardiac glycosides occur in certain plants (digitalis, strophanthus, urginea and others) and are biologically active as cardiac muscle contractants. In general, glycosides can be separated on conventional C_{18} HPLC phases.[323,324] GC separations require modification, such as trimethylsilyl derivatization, prior to analysis.[324–326]

6.20 Hormones

Mueller et al.[327] reviewed methods for analyzing performance-enhancing glycoprotein hormones by GC/MS. Some early LC/MS methods for analyzing hormones (also see sections 6.17 and 6.32) were summarized by Vouros and Karger.[328] Other reviews of both LC/MS and GC/MS were published by Shackleton[329] and Bowers[330] for steroids, and anabolic steroids and peptide hormones, respectively.

6.21 Mycotoxins

Separations of mycotoxins such as coumarins are probably most often performed by HPLC.[331] However, Betina[332] listed many mycotoxin methods (462 references) employing both HPLC and GC. Aflatoxins, ochratoxin A [303-47-9], trichothecenes, zearalenone [17924-92-4] and patulin [149-29-1] were among the mycotoxin analyses reviewed by Scott.[333]

6.22 Nitrosamines

Although they are sometimes used as antitumor agent pharmacophores, some nitrosamines are alkylating agents that invoke carcinogenic activity. The deleterious effects of using tobacco goods may partially be due to the presence of nitrosamines in these products.[334,335] The general public became alarmed when analytical chemists began to find potentially dangerous nitrosamines in many unexpected places such as baby bottle rubber nipples and pacifiers,[336,337] fried bacon[338] and protective gloves.[339] Nitrosamine carcinogenocity may occur by methylation of DNA residues, which can be analyzed by HPLC following hydrolysis. Kawasaki et al.[340] used this technique to measure cytosine derivatives on a SCX HPLC phase.

6.23 Nucleosides/Nucleotides/Bases

Under the hydrophobic mechanism of HPLC reversed-phase column retention, the elution order (and also the order of polarity) of the titled constituents of nucleic acids is: nucleotides > nucleosides > bases. Bases and nucleosides[341,342] are generally sufficiently retained and relatively easily separated on C_{18} phases. Some C_{18} phases may also give adequate retention for simple mixtures of nucleotides. The more lipophilic nucleotides may require special polar interactions for retention, such as those available on IBD reversed phases, or standard normal phases (see section 2.5). Alternatively, the chromatographer might take advantage of the negative charge of the phosphate moiety of the nucleotide molecule in choosing an anion-exchange packing to attain sufficient retention.[343] Reviews have recently been published on HPLC separations directly related to these compounds.[344–349]

Nucleotide and nucleoside samples analyzed by GC/MS are often first hydrolyzed to smaller units. Purine nucleosides are easily acid hydrolyzed to the corresponding free base and pentose.[350,351] However, pyrimidine nucleosides are more resistant to acid hydrolysis. Nucleosidases may be considered for pretreatment, since they hydrolyze both types of nucleoside. The base is then derivatized to a more volatile form, usually with a silane reagent. Columns typically contain DB-5 or SPB-5 phases. The final MS analysis step may provide useful information as biological markers for cancer, AIDS (acquired immunodeficiency syndrome), and other clinical applications.[352–354]

6.24 Parabens

Parabens are most often analyzed by reversed-phase HPLC using a C_{18} or C_8 phase. These phenolic esters have two major uses in pharmaceuticals. They are frequently used as internal standards for drug analysis[355–358] and they are present in a variety of formulations as preservatives/excipients. Pharmaceutical preservatives may include methyl,[359,360] ethyl,[359,361] propyl,[359,360] isopropyl,[360] *n*-butyl,[359,360] and/or isobutyl[360] parabens. It is noteworthy that paraben ''preservatives'' might actually participate in certain pharmaceutical degradation pathways, such as interactions with sorbitol [50-70-4] and/or glycerol [56-81-5].[361]

6.25 Peptides

A wide variety of peptide types (also see sections 6.4 and 6.18) and polarities exist and so, too, there is a diversity

of phases that separate them. Review articles summarize choices of reversed-phase, SEC, ion-exchange, hydrophobic interaction, and other phases for peptide separations.[362,363] Reversed-phase packings, specifically, are covered by Kirkland et al.[364] Evidence provided by Thunecke et al.[365] suggests that a C_{18} phase catalyzes isomerization of *cis-trans* peptidyl proline dipeptides. Because of this and other limitations of silica-based packings, nonsilica peptide columns have also been investigated. Certain polymer phases are stable throughout the pH range showing increased selectivity for peptides compared to conventional silica-based reversed-phase packings, but suffer in that they are less pressure stable and may shrink and swell in particular solvents.[366] Polymer phases that contain polar groups are more favorable for peptide and proteins.[367] Alumina (a Lewis acid) modified with C_{18} chemistry forms phases that are too active and are not suitable for peptide separations.[368]

Chiral separations on simple peptides have been accomplished on molecular imprint,[369,370] affinity[371] and brush-type[372,373] columns. CD chiral phases of various sizes (α-, β- or γ-CD) may be chosen depending on the size of the peptide (see section 5.7), as exemplified by Florance and Konteatis.[374] The primary amine residue of peptides can also be taken advantage of (see section 5.7) by performing chiral separations on crown ether columns.[375]

Peptide and protein separations prevalently use trifluoroacetic acid in the mobile phase. Acid exposure to some reversed-phase columns may catalyze hydrolysis of the bonded phase.[376] Therefore, acid-stable columns are particularly important for these classes of compound (see section 2.4). Another packing consideration is the pore size. The packing material should be chosen so that the solute peptide length is smaller than the pore size of the particle. For medium to larger peptides, a 300-Å pore size is optimum.[377] Smaller peptides may be used on the more universal 100-Å or 120-Å pore size packings. Packings of 200-Å pore size are also commercially available. Selection of too large a pore size packing is not necessarily desirable, since larger pore particles contain less surface area and, hence, display less retention. When performing calculations for optimum pore size, it is important not to overlook that the manufacturer's listing of the pore size is for the bare particle before bonding. A catalogued 120-Å C_{18} phase actually has an effective pore size somewhat less than that, since the bonded C_{18} molecule occupies space within the pore.

GC/MS peptide analysis involves hydrolyzing the peptide and then derivatizing the individual amino acids or fragments before injection. Columns include DB-1,[378] BP-5,[379] and PS255.[380] One particularly interesting publication by Cano[381] used this general procedure to characterize 2- to 135-million-year-old bacteria. Study of ancient bacteria might lead to production of novel antibiotic, fungicidal, etc., proteins and peptides.

6.26 Pharmaceutical Processing Solvent Residues

Granules, tablets, film coatings and plastic sealants used for pharmaceutical drugs may contain harmful solvent residues. Analytical monitoring of these solvents is accomplished by headspace GC analysis using phases such as methyl silicone-coated columns. Foust and Bergren[382] developed a separation method for 27 solvents which required just 20 min.

6.27 Phenylalkylamines

Phenylalkylamines (also see section 6.17) are important structures in pharmaceutical drug design and analysis. The solute's basic residue is subject to active silanol interaction resulting in peak tailing. Active C_{18} phases typically show tailing, even when low-pH mobile phases are used in the attempt to protonate the active silanols.[383,384] Similarly, Murayama et al.[385] found that a titania C_{18} phase is very active for phenylalkylamines. Base deactivated reversed-phase HPLC packings are the best choice for these solutes (see section 5.2).

Maurer[386] performed GC/MS analysis on some derivatized amphetamine designer drugs using a methylsilicone-coated column. For chiral separations of primary amine phenylalkylamines, chiral crown ether columns (see section 5.7) may be utilized.[387]

6.28 Porphyrins

Naturally occurring cytochromes contain iron–porphyrin groups involved in electron-transfer systems or hydroxylation reactions. Hematoporphyrin compounds, which are tumor localizers, have been separated by HPLC on C_{18}[388] or C_8[389] phases with UV detection at 360–400 nm. A bare silica normal-phase column has also been used by Dellinger and Brault.[390] Conventional C_{18} phases were utilized in separating other porphyrin compounds including porphyrin c [68045-92-1] and *N*,*N*′-diacetylporphyrin c [31444-63-0],[391] and porphyrin ether glycerides.[392] Tin protoporphyrin [14325-05-4] and other metalloporphyrins were separated on a DVB phase.[393]

6.29 Procainamides

Antiarrhythmic procainamides are separated on a variety of reversed-phase columns including C_{18},[394,395] hexyl,[396] cyano,[397,398] and phenyl[399,400] packings. Gisch et al.[401] found a *t*-butyl phase gave better peak shapes than an *n*-butyl phase, presumably owing to improved shielding of undesirable silanol interactions by the former bulky substituent. Although procainamides

are not as problematic regarding tailing as are tricyclic antidepressants, they still are sensitive enough to be useful as a first test for packing silanol activity. Several column manufacturers have adopted these solutes in quality control analysis of their bonded phases. Procainamides are also used as internal standards in many HPLC analyses including ranitidine [66357-35-5][402] and propranolol [318-98-9].[403]

6.30 Profens

The profens (also see section 6.5) are readily separated on common C_{18} phases.[404–406] Profens may display good peak shape on active type A packings since they are acidic in nature, but type B phases also perform well (see section 5.1). Enantiomer separations of profens is well studied, including isolations on brush-type,[407] cellulose,[408,409] L-leucinamide,[410] OVM,[411] AGP,[412] ergot alkaloid,[413] avidin[414] and CD[415] phases.

6.31 Proteins

The same generalities associated with the chromatography of large peptides (see section 6.25) also hold true for proteins. Reviews have been published on the choice of phase and mode of separation for protein separations, including reversed-phase, hydrophobic interaction, ion-exchange, gel permeation, bioaffinity, and other types.[416–419] More polar stationary phases are desirable in cases where retention of protein integrity and function is needed. Reversed phases denature proteins, thereby destroying their biological activity. A hydroxyethyl methacrylate phase by Coupek and Vins[420] exemplifies a ''protein-friendly'' phase.

Pore sizes become an important factor in selecting phases for larger protein analytes. The pore should be adequately large enough to accommodate the solute. Packings of 300 Å are of sufficient size for most applications. For proteins approaching a molecular weight of about 500 000 Da or more, a 500-Å phase may be the best choice.

Proteins are somewhat unique in that there is no typical adsorption–desorption mechanism normally occurring in reversed-phase separations. Instead, the proteins apparently stick to the packing material until a ''magical'' ratio of % aqueous : % organic mobile phase composition is reached under gradient conditions, which releases the proteins from the phase. Another particular trait of some peptides and proteins is that they may adhere to SS column and frit surfaces. For this reason, some chromatographers prefer to run protein HPLC separations using all PEEK® connective tubing and column hardware. More extensive studies in this area are needed to quantitate protein interaction with various material types.

6.32 Steroids

Both reversed-phase and normal-phase columns may be used for analyzing steroids (also see sections 6.4, 6.5, 6.17 and 6.20). The cyano phase works by either mechanism, depending on the mobile phase employed. It gives excellent separations, but is often overshadowed by the use of the more familiar C_{18} phase. Reversed-phase methods exist for anabolic steroids,[421,422] corticosteroids,[423–427] bile-acid steroids,[428] cholesterol steroids,[429] phytoecdysteroids,[430,431] brassinosteroids[432,433] and oxysterols.[434] An interesting property of steroids in chromatographic separations is that they tend to show improved separations at lower temperatures, akin to chiral separations.[435]

Low-volatility steroids can be analyzed by GC/MS,[436] including the ecdysteroids.[437] Steroid profiling is another good application for GC/MS analysis as reviewed by Honour.[438]

6.33 Sulfur Drugs

Reversed-phase C_{18} HPLC packings are most often used for analysis of sulfur compounds related to pharmaceutical applications. The antibacterial sulfa drug, sulfadoxine [2447-57-6], was measured in plasma by Astier et al.[439] and Kohl et al.[440] determined disulfiram [97-77-8] and sulfamethoxazole [723-46-6] in urine. Sulfatrim [723-46-6] dissolution[441] and elemental sulfur [7704-34-9] in pharmaceutical preparations[442] testings were also conducted on C_{18} phases. Dangi et al.[443] measured sulfur mustard [505-60-2] in blood samples on a C_{18} phase with UV detection at 200 nm.

Consumer concern over the practice of routinely adding antibiotics to animal feeds has led to the development of methods to analyze these additives in food products. Houglum et al.[444] determined sulfamethazine [57-68-1] in animal feeds with a C_{18} phase. The additives may become incorporated in the meat products, which also is desirable to analyze for health reasons. Thus, Milner et al.[445] resolved sulfadimethoxine [122-11-2] in fish fillets. Sulphadiazine [68-35-9], sulphadimidine [57-68-1], sulphadimethoxine [122-11-2], sulfadoxine [2447-57-6], sulfamerazine [127-79-7], sulfamethoxazole, sulfamonomethoxine [1220-83-3], sulfaquinoxaline [59-40-5], sulfathiazole [72-14-0] and sulfasomidine [515-64-0] were measured in beef, chicken and pork meats.[446] Patthy[447] analyzed sulfaquinoxaline in chicken meat and liver.

Chiral separations for *N*-aryl thiazolinones and their derivatives were run on a brush-type phase.[448] A dimethylsilicone phase was used for GC/MS analysis of anticarcinogen components in garlic extract.[449]

6.34 Taxol and Related Compounds

Taxol [33069-62-4] and related compounds are under intense study for their antitumor and antileukemia activities. These natural products are extracted from yew trees for experimentation and drug development. Chromatographic analyses have been developed for isolating the products from the yew bark, leaves and/or stems, using C_{18} or C_8,[450–453] cyano,[454–456] phenyl,[456–458] porous graphitic carbon,[459–461] PFP,[98,462] and special phases designed especially for taxol separations.[463,464] Limited supplies of yew trees prompted research into growing cell cultures to be harvested for their taxol production. Analytical and preparative methods have been developed for this purpose.[465–468] Methods have also been developed for monitoring taxol levels in experimental mouse plasma models[469–471] and human biological fluids and tissues.[472–482]

6.35 Terpines

In general, GC/MS is currently the leading technique in analyzing terpines (also see section 6.4). For example, the naturally occurring α-terpineol [98-55-5] is an antiseptic drug found in petitgrain oil, long leaf pine oil, cajeput oil, gentian roots and other sources. It has been analyzed on PEG phases,[483,484] and a cholesteryl acetate phase.[485] Separation of the enantiomers has been investigated on substituted CD phases.[483,486,487]

6.36 Tetracyclines

Comparisons were run between several C_{18} and C_8 phases for the assay of tetracycline hydrochloride. Under various conditions the C_8 phases performed as well[488] or better[489] than the C_{18} phases. Polymer phases appear to offer advantages over even base deactivated C_{18} phases in peak shape, separations and recoveries of oxytetracycline [6153-64-6], tetracycline [60-54-8] and chlortetracycline [64-72-2].[490] Although tetracycline is not a particularly large molecule, 1000-Å pore polymer particles seem to be optimum for this solute.[491,492]

In addition to urine[493] and serum[494] analyses, tetracycline is measured in meat, milk and cheese owing to health concerns.[495] An HPLC method was also developed for this drug in discolored teeth, which was found to be caused by incorporation of minocycline [10118-90-8] into the dentine and enamel.[496]

6.37 Tricyclic Antidepressants

Drugs within the class of tricyclic antidepressants represent some of the most challenging compounds to obtain good symmetry in HPLC separations. They are relatively strong bases that can have undesirable potent interactions with active silanols. Type B reversed-phase silica packings are highly recommended for these compounds. Most literature separations using C_{18} phases, whether they are deactivated or not, use ion-pairing[497,498] or ion-suppression,[499,500] additives, and/or acidic mobile phases.[501,502] Acidic mobile phases with cyano phases often provide better peak shape than hydrocarbon phases. This is reflected by the appearance in the literature of several publications using cyano columns.[503–508] Mixed phases have also been used to improve peak shapes of tricyclic antidepressants.[509] An approach to choosing the best stationary phase is described by Kirkland and Henderson.[510] Some direct chiral separations of tricyclic compounds were performed on an AGP (see section 5.7) phase.[511]

Separations by GC are not as prevalent as HPLC methods. Columns used include DB-1,[512] OV-1 and OV-25[513] and SPB-1.[514]

7 ASSOCIATION OF OFFICIAL ANALYTICAL CHEMISTS AND UNITED STATES PHARMACOPEIA METHODS

Appointed volunteers from all over the world perform collaborative validation work in providing the AOAC (Association of Official Analytical Chemists) Official Methods. The studies are designed to establish accuracy, precision, sensitivity, range, specificity, ruggedness, limit of measurement, practicality and other parameters of methods under typical laboratory conditions. The methods are used in government regulations, various commercial product analyses, legal proceedings, and in requirements for some national and international trades. Collaborative study reports for first action methods are published in the *Journal of AOAC International*, while both first and final action methods are published in the compendium, *Official Methods of Analysis*.

The United States Pharmacopeia (USP) provide similar services in developing methods. Regarding bonded phases, a USP method may specify a particular packing type. A list of some USP column classifications is shown in Table 4.

Other assistance available to the chromatographer includes a large selection of applications available from the various commercial column manufacturers. Although most applications are run with standards rather than ''real-life'' samples, the general separations and retention characteristics furnish a good starting point for column selection and chromatographic conditions. Many chromatography column companies offer technical support to assist in the decision making, albeit somewhat biased, naturally, towards the manufacturer's products. The largest convention, by far, for HPLC and GC column manufacturers is the yearly Pittsburgh Conference normally

Table 4 USP column coding system

USP column designation	Description	USP column designation	Description
L1	C_{18} chemically bonded to porous 3–10-μm silica or ceramic microparticles	L18	5–10-μm porous silica bonded with cyano and amino groups
L2	C_{18} chemically bonded to silica gel with a controlled surface porosity bonded onto 30–50-μm solid spherical core	L19	9-μm SCX resin composed of sulfonated cross-linked styrene–divinylbenzene copolymer in the calcium form
L3	5–10-μm porous silica	L20	5–10-μm porous silica bonded with dihydroxypropane groups
L4	Silica gel with a controlled surface porosity bonded onto 30–50-μm solid spherical core	L21	5–10-μm rigid, spherical styrene divinylbenzene copolymer
L5	Alumina with a controlled surface porosity bonded onto 30–50-μm solid spherical core	L22	A 10-μm cation-exchange resin made of porous polystyrene gel with sulfonic acid groups
L6	Sulfonated fluorocarbon polymer which acts as a strong cation exchanger coated on 30–50-μm solid spherical core	L23	A 10-μm ion-exchange resin made of porous polymethacrylate or polyacrylate gel with quaternary ammonium groups
L7	C_8 chemically bonded to porous 5–10-μm silica or ceramic microparticles	L24	A semi-rigid hydrophilic gel consisting of 32–63-μm vinyl polymers with numerous hydroxy groups on the matrix surface
L8	Aminopropylsilane chemically bonded to porous 10-μm silica or ceramic microparticles	L25	A packing with the ability to separate compounds with a molecular weight range from 100 to 5000, especially neutral, anionic and cationic water-soluble polymers
L9	Irregular, 10-μm porous silica bonded with a strongly acidic cation exchanger	L26	5–10-μm porous silica bonded with butyl groups
L10	5–10-μm porous silica bonded with nitrile groups	L27	30–50-μm porous silica
L11	5–10-μm phenyl bonded porous silica	L28	High-purity, 100-Å spherical silica bonded with an anionic function (amine) as well as a conventional reversed-phase C_8 functionality
L13	5–10-μm porous silica bonded with trimethylsilane	L29	Spherical, 5 mm, 80-Å γ-alumina coated with polybutadiene used for reversed-phase chromatography
L14	10-μm silica bonded with a strong basic quaternary ammonium anion exchanger	L30	3–10-μm porous silica bonded with ethyl groups
L15	3–10-μm hexyl bonded porous silica	L31	Latex particles bonded with a quaternary amine attached to a core of 8.5-μm macroporous particles with 2000-Å pores and composed of ethylvinylbenzene cross-linked with 55% divinyl benzene which functions as a strong anion exchanger
L16	5–10-μm porous silica bonded with dimethylsilane	L32	Irregular, 5–10-μm silica bonded with an L-proline copper complex which acts as a chiral ligand exchange packing
L17	7–11-μm SCX resin composed of sulfonated cross-linked styrene–divinylbenzene copolymer in the hydrogen form	L33	A specially processed, pH stable, spherical silica-based packing capable of separating proteins with a molecular weight from 4000 to 400 000
		L34	9-μm SCX resin composed of sulfonated cross-linked styrene–divinylbenzene copolymer in the lead form

held in March, where chromatographers may scout and learn about the newest developments in column phase technology.

ACKNOWLEDGMENTS

The author would like to thank Stephanie Risbon and C. Vernon Bartlett for assistance in preparing this manuscript, and Kent Rauch for his aid in preparing figures. This work is dedicated to my Father.

ABBREVIATIONS AND ACRONYMS

AA	Atomic Absorption
ACE	Angiotensin-converting Enzyme
AGP	α_1-Glycoprotein
AIDS	Acquired Immunodeficiency Syndrome
AOAC	Association of Official Analytical Chemists
ASTM	American Society for Testing and Materials
BaP	Benzo[*a*]pyrene
BSA	Bovine Serum Albumin
CD	Cyclodextrin
cGMP	Continuous Good Management Practices
CLEC	Chiral Ligand Exchange Chromatography
CMPA	Chiral Mobile Phase Additive
CSP	Chiral Stationary Phase
DNBPG	Dinitrobenzoylphenylglycine
DVB	Divinylbenzene Polymer
DZ	Dual Zone
EDTA	Ethylenediaminetetraacetic Acid
FAME	Fatty Acid Methyl Ester
FDA	Food and Drug Administration
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
GC/EC	Gas Chromatography/Electron Capture
GC/FID	Gas Chromatography/Flame Ionization Detection
GC/MS	Gas Chromatography/Mass Spectrometry
GFF	Glycerylpropyl/glycine-L-phenylalanine-L-phenylalanine
GMP	Good Management Practice
HPLC	High-performance Liquid Chromatography
HPLC/UV	High-performance Liquid Chromatography/Ultraviolet
HSA	Human Serum Albumin
IAM	Immobilized Artificial Membrane
IBD	Intrinsically Base Deactivated
ID	Internal Diameter
ISRP	Internal Surface Reversed Phase
LC	Liquid Chromatography
LC/MS	Liquid Chromatography/Mass Spectrometry
LC/NMR	Liquid Chromatography/Nuclear Magnetic Resonance
MFP	Mixed Functional Phase
MS	Mass Spectrometry
NIST	National Institute of Standards and Technology
NMR	Nuclear Magnetic Resonance
ODS	Octadecylsilyl
OVM	Ovomucoid
PAH	Polycyclic Aromatic Hydrocarbon
PEEK®	Polyetheretherketone
PEG	Polyethylene Glycol
PFP	Pentafluorophenyl
PGC	Porous Glassy Carbon
PhPh	Phenanthro[3,4-*c*]phenanthrene
PMM	Polymethylmethacrylate Polymer
PS/DVB	Polystyrene/Divinylbenzene Copolymer
PVA	Polyvinylalcohol Polymer
QA/QC	Quality Assurance/Quality Control
QSRR	Quantitative Structure–Retention Relationships
RMS	Root Mean Square
SAX	Strong Anion-exchange
SCX	Strong Cation-exchange
SEC	Size Exclusion Chromatography
SHP	Shielded Hydrophobic Phase
SOP	Safe Operating Procedures
SPE	Solid-phase Extraction
SPS	Semipermeable Surface
SRM	Standard Reference Material
SS	Stainless Steel
TBN	1,2-3,4-5,6-7,8-Tetrabenzonaphthalene
TDM	Therapeutic Drug Monitoring
USP	United States Pharmacopeia
UV	Ultraviolet
UV_{max}	Ultraviolet Maximum
UV/VIS	Ultraviolet/Visible
WAX	Weak Anion-exchange
WCX	Weak Cation-exchange

Mass spectrometry (MS) applied to the biological sciences in the pharmaceutical industry covers a broad range of application topics, such as quantitative analysis of drugs in physiological fluids, qualitative analysis of noncovalent complexes, structural analysis to determine chirality and protein sequence analysis. Regardless of the application, electrospray ionization (ESI) is the primary ionization method for transfer of nonvolatile biologics like proteins and peptides into the gas phase for analysis. It is most often used as an interface between high-performance liquid chromatography (HPLC) separation methods and MS. The ESI process converts analytes in solution to ions in the gas phase via electrostatic nebulization at atmospheric pressure. It is characteristic of ESI to produce multiply charged analytes in a concentration-dependent manner that is sensitive to changes in solvent, pH and ionic strength. A high voltage is applied to a liquid containing analytes as they traverse a capillary, and when the liquid droplets exit this capillary at atmospheric pressure they are directed into the source region of a mass spectrometer where desolvation is completed. Ions are then focused by an electronic gradient across a series of lenses and separated by mass/charge (m/z) using various mass spectrometer designs. Currently, the two most popular mass separation devices are quadrupoles (either single or triple quadrupole (TQ)) and ion traps (ITs). Both types of mass spectrometers are used with ESI to achieve sensitivities as low as attomoles (10^{-18} mol) of analyte injected onto a microcapillary HPLC column. The type of analyte, as long as it is capable of accepting a charge (addition of H^+ or loss of charge in negative ion mode) is relatively transparent to ESI and so a diverse range of analyte classes with disparate molecular weights can be ionized, from peptides (500–5000 amu) to proteins (10 000–100 000 amu). Depending on the construction of the source, ESI can be carried out with reversed-phase HPLC at flow rates from 200 nL min^{-1} to 2 mL min^{-1} and also with capillary electrophoresis. The ease of use of ESI compared to prior techniques like fast atom bombardment

has made it very popular with biologists, chromatographers and chemists who might not otherwise have been interested in MS. In fact, for many scientists ESI has made MS almost as ''user-friendly'' and thus accessible as an ultraviolet (UV)–visible detector for HPLC.

1 INTRODUCTION

The modern pharmaceutical laboratory utilizes MS for many purposes, including basic biological research, quantitative analysis, qualitative analysis and routine monitoring for quality control of products. Before the mid-1980s and fast atom bombardment[1,2] ionization, MS was mainly used for the quantitation of small volatile organic molecules and structural analysis via chemical and electron impact ionization. The incorporation of MS into all aspects of pharmaceutical research was made possible by two developments in the late 1980s, specifically the development of two ionization methods, which revolutionized the way in which biological analytical sciences were conducted. These two ionization methods or techniques – ESI[3] and matrix-assisted laser desorption ionization (MALDI)[4] – gained immediate popularity because of their ability to ionize, without significant fragmentation or prior derivatization of analytes, nonvolatile biological molecules such as proteins and peptides. For many laboratories ESI quickly replaced fast atom bombardment as the interface between HPLC and MS,[5] owing to the ease with which it could be adapted to scanning instruments such as quadrupoles. Furthermore, the ESI process allowed simple quadrupole instruments with a limited m/z range to detect analytes outside the m/z range of the instrument, because of the addition of multiple charges to analytes during the ESI process.

Qualitative MS is often used to help biologists gain insight into biological processes or systems. Understanding noncovalent, intermolecular interactions between two macromolecules, between a small molecule and a macromolecule or simply mapping disulfide bonds within a protein can be performed much faster with MS than traditional methods.[6] Studies similar to these can provide details about how a receptor molecule may bind a ligand, providing important information prior to crystal growth for crystallographic studies. For instance, cross-linking a ligand to a receptor, followed by enzymatic digestion and MS analysis, provides information about sites juxtaposed under native conditions that is valuable for the interpretation of crystallographic data. If the receptor–ligand complex cannot be crystallized, then the MS data may be the only route to understanding the interaction.

Quantitative studies have been, and continue to be, an important application of MS. With the advent of ESI, the variety of molecules accessible for analysis became much wider than when electron impact, chemical ionization and fast atom bombardment were the only good choices for ionization. Generally, MS has been used to quantitate small organic molecules (<500 Da) in plasma and urine. However, even large molecules such as proteins can, with an appropriate standard, be quantitated using ESI or MALDI without enzymatic digestion to peptides. Quantitation of peptides in plasma and urine is remarkably similar to the analysis of small molecules from these matrices. Peptides, however, generally suffer from poor pharmacokinetics after oral administration, which is generally due to the short half-life observed for many peptides.[7] This is often controlled through modification of the structure to prevent rapid digestion by proteolytic enzymes present in the gut and circulatory system.[8]

MS now is also used for routine sequencing of proteins for the drug discovery process. With the advent of DNA and protein databases, MS has replaced Edman chemistry as the method of choice for sequence analysis for all but complete unknowns. The MS sequence methods rely on correlative analysis between tandem mass spectrometry (MS/MS) data that is analyzed by computer algorithms such as SEQUEST[9] and sequences that exist in databases. Edman chemistry[10] will, however, continue to be important for sequence analysis of organisms for which no genome sequence is available and for post-translational modification such as phosphorylation of certain peptide sequences that are intractable to MS methods.

In addition to the use of MS in basic research, the application of this technology for quality control is important. Methods that allow for rapid assessment of drug substance batch-to-batch quality are routinely devised, as are methods for the analysis of peptide or protein purity. After a review of the basic MS instrumentation currently in use and some general aspects of working in an analytical laboratory, examples will be provided for MS applications in the quantitative analysis of peptides in urine, chiral analysis of peptides, comparative MS/MS analysis and thermal denaturation of DNA complexes. All of these topics are of widespread interest and constitute ongoing areas of analytical development in the pharmaceutical science. For many of these applications, the type of analyte used is more or less transparent to the analytical process and thus is useful for small molecules as well as peptides and proteins.

2 BIOLOGICAL MASS SPECTROMETRY

2.1 Mass Spectrometers

At the simplest level, MS consists of three processes: ionization (e.g. MALDI or ESI); mass (m/z) separation

(e.g. time-of-flight (TOF), quadrupole, IT); and ion detection. Ion detection, being mostly MS instrument independent, will not be covered here. Analytes in solution or as crystals on a surface are converted to ions by the ionization process where protons/electrons are added or subtracted to impart some detectable m/z value. Ions are then separated from each other in vacuo based on a process that is dependent on the type of mass spectrometer being used. For protein and peptide applications, the four most common types of mass spectrometers utilized are MALDI coupled to a TOF mass spectrometer and ESI coupled to a TQ, a single quadrupole (SQ) or an IT mass spectrometer. The applications presented in this chapter will focus on ESI and so MALDI coupled with a TOF mass spectrometer will not be reviewed directly.

2.2 Electrospray Ionization

In ESI, the analyte solution passes through a needle to which a high potential (~1000–5000 V) is applied at atmospheric pressure.[11,12] This results in electrostatic nebulization of the liquid, producing charged liquid droplets that are directed to the mass spectrometer inlet, which is at some lower potential than the ESI voltage. As the charged droplets traverse the source region they are desolvated by various processes, depending on the instrument design. The process by which analytes in solution are converted to ions in the gas phase continues to be a topic of debate among research laboratories and will not be discussed further. After desolvation, solvent-free ions are focused through a series of lenses into the mass analyzer. It is characteristic of the ESI process to produce peptide ions bearing multiple charges. The number of observed charge states is a function of the number of ionizable groups contained in the analyte. The observed distribution of charge states can be affected by changes in pH, solvent and tuning conditions.[13,14] For instance, tryptic peptides analyzed by positive ion mode electrospray ionization/mass spectrometry (ESI/MS) at a pH of 3.5 will normally carry at least two charges.[15] This is because the hydrolysis of a peptide bond by trypsin leaves a lysine or arginine amino acid at the carboxyl-terminus of the peptide. In general, peptides and proteins will bear a number of charges in positive ion mode roughly equivalent to the number of basic residues, such as the amino acids lysine, arginine, histidine and proline, present in the sequence. If the protein or peptide is of unknown molecular weight, adjacent charge states can be used to determine the molecular weight. Most instruments come with software to do this deconvolution but it is based on simple algebra. To determine molecular weight from the mass spectrum of an unknown analyte we can use the mass spectrum in Figure 1 as an example. Choose two adjacent charge states suspected of being related and fill in the following equation: $(m_2)/(m_2 - m_1) = (649)/(649 - 433) = 3$. If this algebra produces an integer, as in this case, then the integer represents the number of charges (e.g. in positive ion mode protons or sodium ions) on m_1; i.e. 433 is an $[M + 3H]^{3+}$ ion. If $(m_2)/(m_2 - m_1)$ produces a noninteger, then the adjacent m/z values are not related (i.e. they arise from different analytes or the same analyte but have different charge-bearing adducts). Molecular weight is then obtained from the following equation: $(m_1)(m_2)/(m_2 - m_1) - (m_2)/(m_2 - m_1) = (433)(3) - (3) = 1296$. Note that for the negative ion mode of peptides, protons are removed from the peptide.

2.3 Electrospray Ionization/Quadrupole Instrumentation

Quadrupoles consist of four parallel rods with opposite pairs of rods connected electrically carrying DC and AC voltages of opposite polarity. Voltage is varied across the rods such that at a given moment in time only ions of a certain m/z ratio oscillate in a synchronous and linear path through the filter. All other ions follow a nonlinear trajectory out of the quadrupole and are lost. To produce a mass spectrum, the quadrupole is ''scanned'' across a defined m/z range. A typical scan with a quadrupole instrument takes several seconds, because the AC and DC voltages are varied for a scan and then reset to start again. In contrast TOF and IT mass analyzers acquire an entire mass spectrum in milliseconds. A TOF mass analyzer has a theoretically unlimited m/z range and so is popular for analyzing proteins, whereas quadrupoles and ITs are typically limited in m/z range, thus relying on the multiple charging observed with ESI sources to analyze high-molecular-weight compounds.

A TQ mass spectrometer consists of three sets of quadrupoles that can either transmit all ions (i.e. radiofrequency (RF)-only mode of operation) or function as a mass filter allowing ions of a specific m/z to pass.[16] Generally the first (Q1) and third (Q3) quadrupoles function as mass filters whereas the second quadrupole (Q2) always operates in RF-only mode. When filled with argon (~3–5 mTorr) and with an accelerating voltage applied, Q2 serves as a collision cell, passing all fragment ions from a precursor ion selected by Q1. There are five basic modes of operation for a TQ:

1. In **MS mode**, Q1 or Q3 is scanned to produce a ''main beam'' or standard mass spectrum whereas the non-scanned quadrupole functions in RF-only mode. This scanning mode would provide data that are exactly analogous to the data that one would observe using an SQ instrument.

Figure 1 Results from Liquid chromatography/mass spectrometry (LC/MS) system suitability standard test. (a) Total ion chromatogram (TIC) for 500 fmol of angiotensin and single ion chromatogram (SIC) for the 3+ ion. (b) Abscissa magnified around the SIC of the 3+ ion to show peak shape. (c) Sum of mass spectra across the full width at half-maximum (FWHM) shown in (b) normalized to the 3+ ion and the same mass spectrum with the ordinate magnified 1000×. Data acquired on an SQ scanning 300–1500 amu in 1.5 s.

2. In **MS/MS mode**, Q1 transmits ions of a selected m/z. These ions are accelerated into Q2, which is filled with argon gas to generate fragment ions. These fragment ions are then transmitted by Q3, which is scanned to produce a mass spectrum consisting of fragment ions originating from the Q1-selected m/z ion.
3. In **neutral loss mode**, Q1 and Q3 are scanned simultaneously but with Q3 at an m/z offset, corresponding to a neutral loss of interest (e.g. doubly-charged phosphorylated peptides can be detected by scanning for a neutral loss of 49 m/z (loss of H_3PO_4) that undergoes a facile β-elimination). The resultant mass spectrum consists only of ions that lose the specified neutral m/z fragment.[17]
4. To generate a **precursor ion scan**, Q1 is scanned while Q3 transmits ions of only one select m/z value. Thus, all ions transmitted through Q1 are sequentially fragmented in Q2 and any that produce a fragment ion equal to the m/z value set for Q3 produce the so-called precursor ion mass spectrum.[18]
5. **In-source fragmentation** provides an opportunity for triple MS on a TQ instrument or MS/MS on an SQ instrument, or in negative ion mode as a diagnostic ion scan for loss of phosphate from a peptide.[19] Fragmentation occurs in a high-pressure region of the differentially pumped ESI source, as a result of collisions with atmospheric gases. It is an indiscriminate process where charge states with $n > 1$ are preferentially fragmented by imparting a greater amount of kinetic energy than is necessary to simply focus the ions into Q1. All of the above scan types, 1–4, can be carried out on ions generated by in-source collision-induced dissociation (CID).

The two most commonly used MS modes for quantitation are variations on the MS mode and MS/MS mode described above: specifically, selected ion monitoring (SIM), which is sometimes referred to as multiple ion monitoring; and selected reaction monitoring (SRM), which is sometimes referred to as multiple reaction monitoring. These methods of quadrupole operation are important for quantitative analysis. An example of SIM quantitation is presented in section 5. Generally in quantitative studies, a stable isotope label of the drug substance or an analog similar in chemical properties to the drug substance is added as an internal standard (see section 5, where this is discussed in depth). The internal standard is added at a constant amount to the biological sample prior to any sample preparation. Once the sample has been prepared, it can be injected onto the mass spectrometer. In SIM mode, the mass spectrometer scans a small m/z window (typically <0.4 amu) at the m/z of both analyte and internal

standard. This is repeated continuously over the entire chromatographic run. The areas under the curve for each standard concentration are then plotted, so that a linear regression can be used to calculate the quantity of analyte in each unknown sample. It is important to prepare the standard curve in the same matrix that will be used in the study and that the analysis of standards and samples be reproducible. The second type of method commonly used for quantitation is SRM. This technique has significant advantages over SIM in both selectivity and specificity, resulting in a potential speed advantage. In this mode, the TQ remains in MS/MS mode and continuously switches between two different MS/MS reactions: one for the analyte and one for the internal standard. Specific fragment ions, instead of precursor ions, as with SIM, are used for quantitation. Many laboratories are utilizing SRM quantitation with TQs, to achieve the lowest possible detection limits for potent drug substances. The selectivity and specificity of SRM reduces the amount of chromatography required, thus time-consuming (i.e. costly) chromatography can be avoided. Chromatography is still utilized, but it is done rapidly, where an entire run may only last a few minutes. Generally the analyte is desalted, retained on the column for a short period of time and eluted. With an isocratic method, limited column equilibration is required. With a rapid gradient method, as short as possible column re-equilibration is performed. Samples in very complex matrices[20] can be analyzed with little clean-up prior to analysis owing to the specificity of the MS/MS reaction. The sample clean-up is still required with SRM quantitative studies, owing to the ion suppression effects of salts, proteins, and other endogenous compounds. It is also important to demonstrate, through the analysis of blanks, that no endogenous compounds interfere with the analyte-to-fragment ion transition selected for quantitation because it is the unique combination of analyte mass and fragment ion mass that identifies one analyte from another.

2.4 Electrospray Ionization/Ion Trap Instrumentation

A major difference between a TQ and an IT mass spectrometer is that in an IT instrument the mass analyzer also serves as the collision cell.[21] Quadrupole ITs use RF-only quadrupoles to guide ions from the ESI source into the IT, similar to quadrupole instruments. The mass analyzer is significantly different, however. Two different types of electrodes are used to create the IT: a ring electrode and two end-cap electrodes. Ions enter and leave the trap through holes in the end-cap electrodes and are trapped in a field created by applying an RF voltage to the ring electrode. The magnitude of the voltage determines the frequency and motion of trapped ions. Ions above a certain m/z remain in the trap and are collisionally cooled to stabilize their trajectories with helium gas. This results in a collapse of the sinusoidal cycling of ions from a larger to a smaller trajectory over a short period of time. A mass spectrum is acquired by ramping the RF voltage linearly while applying a small voltage across the end-cap electrodes, which causes ''resonance ejection'' of ions of successive m/z. Resonance ejection refers to ions becoming unstable in the trap and thus being ejected axially through the end-cap electrodes, where they are detected by an off-axis conversion dynode with an electron multiplier detector.

Through this ion trapping/ejecting process, tandem MS experiments (MS/MS) and MS^n experiments are conducted. The process of fragmenting ions in an IT begins by ejecting all ions at larger and smaller m/z than the ion of interest. Once the IT contains only the m/z of interest, the selected m/z value is energized by altering voltages on the electrodes, so that it collides with the dampening gas (helium). Fragment ions are then detected by scanning out all of the ions from the trap, as described above. If sufficient signal persists, further rounds of MS/MS (MS^n) can be conducted by leaving a fragment ion of interest in the trap for additional fragmentation events. The amount of energy imparted to the trapped ion can be varied with a parameter referred to on some instruments as the relative collision energy. Other parameters that can be varied on an IT include the number of ions allowed to enter the trap in any one event and the number of such events performed in replicate for averaging purposes (i.e. increasing signal-to-noise). Commercial IT mass spectrometers have data-dependent fragmentation capabilities and are therefore ideally suited to liquid chromatography/tandem mass spectrometry (LC/MS/MS).

3 SAMPLE HANDLING CONSIDERATIONS

3.1 Sample Handling for High Sensitivity

This field is better known as microsample handling and is of significant importance to those working with any sample that can be described by the phrase ''the world's supply''. This usually means that the biologist is nervous about handing over six months' worth of work to someone with no direct appreciation for the precious sample. Or it may mean that the samples are worth thousands of dollars and the study (e.g. clinical trial) cannot be repeated easily. There are some simple rules worth mentioning that can be followed for working with peptides and other small molecules. Generally, almost any transfer or purification step applied to a sample will reduce the quantity by 50%. This is a generalization of course, but the point is to plan carefully the route from

tube to MS so as to avoid potential sample loss. Complete lyophilization to dryness should be avoided because some peptides (and other analytes as well), once dried in a polypropylene tube, will not go back into solution. It is of course impossible to predict a priori which will behave this way. Often new columns will irreversibly adsorb a portion of the sample, thus new HPLC columns should be preconditioned prior to injecting a valuable sample. Finally, the mass spectrometer should be tuned using an analyte that is as near identical to the sample and under the same conditions that the sample will be introduced as possible. Failure to tune the MS under appropriate conditions can easily negate any advantage provided by careful sample handling.

3.2 Chromatographic Considerations

In the field of Proteomics,[22] working with the smallest i.d. capillary HPLC columns possible is a requirement in order to avoid sample loss and to optimize sensitivity.[23,24] Samples, often present at the limit of detection, are extracted from polyacrylamide gels and any manipulation of sample must be minimized. LC/MS sensitivity is optimized by using 50-μm i.d. capillary liquid chromatography (LC) columns packed using stainless-steel chambers (Mass Evolution, Houston, TX) pressurized to 1000 psi. Samples are loaded directly using the same pressure chamber into the capillary column without any chance for loss present in a normal injector where transfer to a syringe is required. The fused silica capillaries (50 μm i.d.) are slurry packed to 10 cm with C18 silica beads in 70% ethanol.[25–27] Porous frits are placed at the capillary terminus to hold the packing in place by sintering underivatized silica beads (LichroSorb Si60) in a flame. Peptides are eluted quickly with a fast linear gradient of 0–60% solvent B in 15 min at 150 nL min^{-1}. Standard HPLC pumps operated at 50 μL min^{-1} can be used for the microcapillary column described above using a precolumn restrictive flow splitter that is 50 μm i.d. and 200 cm in length. This fast gradient method, together with a trace amount of ion pairing reagent, maximizes the chromatographic resolution and produces a sharp elution profile. Typical solvents are aqueous with 0.2% acetic acid and 0.005% heptafluorobutyric acid in one pump and acetonitrile alone in the second pump. Acid is not needed in solvent B for good chromatography and its addition only increases the chemical noise observed in the mass spectrometer. For such small columns, microspray sources are easily and economically constructed from commercially available baseplates and parts (Mass Evolution, Houston, TX), such as a Valco stainless-steel union to which the ESI voltage is applied. Capillary columns terminate inside the Valco union and a fused silica capillary (10 cm × 50 μm × 180 μm) manually tapered to ~5 μm serves as an emitter. No sheath gas or liquid is necessary for such small flow rates. This same device can also be used in negative ion ESI/MS. These techniques have been used to great advantage for sequencing and identifying peptides present in extracts at the very limit of detection by ESI/MS in the fields of apoptosis[28] and immunology.[28–30] Additional examples of the use of microcapillary columns to solve structural problems in biology can be found at the World Wide Web site: http://staff.washington.edu/goodlett.

3.3 Electrospray Ionization Advantages

An additional advantage can be made of the concentration-dependent nature of ESI, which allows the flow of liquid through an ESI source to be decreased or modulated relative to some normally constant flow rate during a separation without sacrificing sensitivity.[31] The advantage provided by a reduction in flow through the ESI source can be thought of as follows. If at a given moment in time (i.e. one scan) 100 analyte molecules pass through the ESI source and there is current available to convert only ten analytes to ions in the gas phase, then 90 will be wasted. By reducing the flow through the ESI source, the available ESI current can be utilized more efficiently. Consider the following simplified example where flow is reduced and the chromatographic ''peak'' broadened such that 25 analytes instead of 100 pass through the source during one scan. Now, with the only experimental change being reduced flow through the ESI source, such that there is still enough current available to convert ten analytes per scan to ions, only 15 analyte molecules are wasted per scan. The next three MS scans across this broadened ''peak'' will detect, in turn, 30 analytes as ions. So, instead of 10% of the sample being analyzed, 40% is analyzed via this reduced elution speed process. This may seem insignificant, but it has proven to be important for both electrophoretic and capillary liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS) applications.[5,32] Several names have been used to describe this process, including ''peak parking''[33] and ''voltage drop'';[34] regardless of the name, it is the concentration-dependent nature of ESI that allows more time for analysis across a given chromatographic area without sacrificing sample.

4 GENERAL LABORATORY

4.1 Following Good Laboratory Practice

Good laboratory practice (GLP) regulations are a management-based quality system enforced by the Food and Drug Administration (FDA) for nonclinical studies.

It is intended for nonclinical laboratory studies that support applications for research or marketing permits for products regulated by the FDA. Laboratory analysis done for clinical trial support is also expected to be done under GLP. In general, following GLP is mainly about using a commonsense approach to laboratory management. Scientists are asked to record all work in a logical and reproducible manner such that it can be easily repeated or reconstructed. It involves signing and dating all notebook entries so that a trail is left for decision-making in future experimental design and for auditors. Standard operating procedures should be developed and adhered to for instrumentation used in the various studies. Instrument maintenance logs are kept for each piece of equipment so that trouble-shooting can be carried out logically and orderly. Instruments should be tested routinely to ensure that they are in good working order. When a system that is routinely tested using the same conditions fails, then logical systematic procedures should be in place to correct the problem. Each set of experiments should include, at the very least, a set of system suitability checks (i.e. standards and blanks run under conditions identical to the unknowns) placed at the beginning and end of each data set to ensure that the instrument or system is, and has, functioned properly over the course of the analysis.

For LC/MS systems there are four tests that the system suitability standard can assess:

1. Is the HPLC system functioning properly?
2. Are the solvents clean?
3. Is the mass spectrometer tuned and calibrated properly?
4. Is the HPLC column and associated plumbing in good condition?

All of these questions can be answered by one LC/MS analysis performed prior to analyzing real samples. To answer these questions a system suitability standard is designated for the laboratory LC/MS work. It should be an analyte in the same class as that being analyzed or a well-characterized sample. For example, a system suitability test for microcapillary high-performance liquid chromatography/mass spectrometry (HPLC/MS) using a 50-μm i.d. × 10-cm C18 column could be the analysis of 500 fmol of angiotensin. The peptide is injected onto the capillary column and then eluted under standard linear gradient conditions (Figure 1a). The results obtained are analyzed in light of the above questions. If the HPLC system has functioned properly to deliver solvents as programmed, then the elution time for the peptide will be reproducible. If elution time is outside of the expected range, then either the HPLC system is not functioning as programmed or perhaps the column is beginning to fail. The peak shape should be symmetrical and elute over a short time period of 10–15 s (Figure 1b). If the peak is too broad or not symmetrical, then there may be a problem with the chromatography or perhaps additional dead volume has been introduced somewhere in the HPLC system. If the HPLC/MS system is working properly, then the signal-to-noise ratio of the analyte should be above a preset value. If the signal-to-noise ratio of the analyte is below an acceptable value, then perhaps the solvents should be changed or the mass spectrometer cleaned. For a 500-fmol angiotensin injection on the above-mentioned capillary column dimensions, a signal-to-noise ratio of at least 1000 : 1 should be attained at the apex of the chromatographic peak (Figure 1c). Finally, the calculated and observed molecular weight for the analyte (angiotensin) should match closely. Of course many of the potential symptoms and problems in an HPLC/MS system are related and some skill is needed to ascertain the exact cause of decreased system performance. However, a simple, well-designed, well-characterized, robust system suitability test carried out prior to the analysis of samples would provide confidence in the observed results and should enable the novice operator to begin trouble-shooting a complex scientific instrument if something were to go wrong.

4.2 Automation

Almost every step in the sample analysis process can be and has been automated. Some automated processes are more efficient than others, but all automation is driven by the high costs of drug discovery and production. This cost includes employee costs and the years of research prior to discovery that are followed by methodical FDA testing requirements once a new drug candidate has been identified. The desire for higher throughput in pharmaceutical companies can be observed easily from the combinatorial chemistry initiatives being employed at almost all companies. The need for larger compound libraries, in the hopes of finding better lead candidates, has relied heavily on the automation of numerous synthetic procedures. MS has been utilized heavily in the combinatorial chemistry field, performing rapid molecular weight measurements, high-throughput purification, and decoding libraries from hundreds of combinatorial chemistry samples per day. Almost all of the MS instruments utilized in the combinatorial field are part of an automated system, where multiple probe injectors, high-capacity autosamplers, fraction collectors, analog detectors, and liquid delivery systems are used together. With the increased size in focused libraries, additional needs have been placed on the discovery research groups responsible for lead identification, development, and selection. These groups have begun to utilize robotic liquid handlers, 96-well solid-phase extraction (SPE), fast generic gradient methods, and as many mass spectrometers as necessary to analyze

samples as rapidly as possible from a variety of in vitro and in vivo screens. From sample work-up to data analysis, devices have been built that free chemists for nonroutine tasks that require problem-solving skills. This drive to increase throughput and efficiency can be beneficial for scientists operating in this environment. The increased use of automation may enable employees to focus on the creative processes of managing projects, understanding processes, and interacting with other scientists to understand better the important scientific problems facing society today.

In the field of protein discovery science, data-dependent analysis is commonly used in a first-pass analysis of samples.[35] The entire HPLC/MS analysis is automated once the scientist loads a sample into the autosampler tray. The number of injections per vial and the injection volume can be controlled by various instrument programs. The time-consuming data analysis process can also be automated to some degree; indeed the scientist can load a sample in the evening and data printouts are waiting in the printer bin when the scientist returns the next day. With modems and networking, progress can be monitored and analyses interrupted remotely if necessary to avoid waste of valuable samples.

As an example, a routine for sequencing peptides would be designed to select an ion for MS/MS, based on ion current intensity. As carried out on a TQ instrument, the mass spectrometer would be set-up (i.e. tuned) to operate with Q2 at a constant argon pressure of 3 mTorr. The offset on Q3 is increased to compensate for the dampening effect of this gas. No fragmentation is observed from such low-energy collision with the gas because the ions during a normal MS scan are not accelerated into the collision gas. However, once the instrument control language (ICL) procedure selects an ion for MS/MS, then the Q2 offset is increased as a function of the m/z value selected for MS/MS. More energy for fragmentation is required for higher m/z values than smaller, but less for higher charge states than lower ones, because the energy barrier to fragmentation is lowered by Coulombic repulsion when more than one charge is present. For this automated MS/MS process the instrument is not optimized for a specific ion of interest and so Q2 offset energy is increased slightly during three consecutive MS/MS scans such that the final summed MS/MS spectrum is a composite of MS/MS scans carried out all on the same ion but at various energies. This rotation of energy compensates for the lack of operator input during the process and produces readily interpretable spectra. Once the three MS/MS scans for the selected ion are acquired, the ICL procedure returns the mass spectrometer to full scan or simple MS mode and the process of ion selection begins again. The ion just selected for MS/MS goes into a list of ions to prevent it from being immediately selected again should it prove to be still the most intense ion in the first scan after switching back to MS mode. In this manner, a 100 MS/MS spectra can be acquired in a single LC run. On an IT where scans are of the order of milliseconds rather than seconds, many more MS/MS spectra can be acquired per LC run. This advantage can be of value when seeking to get as complete a coverage as possible on the peptides present in a tryptic digest. Additional information and ICL routines can be found at the World Wide Web site: http://depts.washington.edu/~ruedilab/aebersold.html.

4.3 Managing Instrument Time

Mass spectrometers, being so-called universal-type detectors, rarely sit idle once installed. If the instrument is easy to use and delivers the expected results then chemists and biologists will keep the instrument busy. Mass spectrometers tend to be set-up in three broad categories of user: the single-operator instrument, which is usually a more complicated design or usage; the open-access instrument, for multiple users who are often the least experienced; and the multiple-operator instrument, which is used by many experienced users. In the last 10 years mass spectrometers have become more user-friendly to the point where instruments are more often sold today to chemists, chromatographers or biologists with no prior experience in setting them up. This ease of use has made the open-access laboratory and the multiple-user set-up possible where before specialists were needed just to maintain the instrument. Many open-access instruments are usually maintained by an analytical department, or other departments that are heavy users of MS instrumentation simply hire at least one person trained in MS. Manufacturers have made interfacing to a mass spectrometer easy for the novice by using computer software such as Windows NT, with which most people are familiar. For many MS instruments, operation may be as easy as any other laboratory instrument, such as a gas chromatography, HPLC or UV–visible spectrophotometer.

5 QUANTITATION OF PEPTIDES BY ELECTROSPRAY IONIZATION/MASS SPECTROMETRY

5.1 Analysis of Peptides in Physiological Fluids

Analysis of trace levels of drugs in urine by automated procedures that avoid SPE is of particular interest in the pharmaceutical sciences. Benefits to direct sample analysis over SPE include a decrease in sample preparation

time and a reduction in nonspecific losses that can occur during SPE. Although SPE produces adequate sensitivity for most studies, it is time-consuming and costly. Methods that allow peptides to be analyzed directly from plasma or urine are also of interest because of the low half-life of most peptides in physiological fluids. For a small peptide such as thymopentin (Arg-Lys-Asp-Val-Tyr), it can be as low as 30 s. The limited bioavailability of orally administered peptides is due in large part to enzymatic and acid hydrolysis in the gut and stomach.[7,8] Resistance to hydrolysis may be improved by modification of the amino- and carboxyl-terminii. Even so, methods that provide rapid processing of peptides in physiological fluids for analysis are needed for pharmacokinetic studies where the concentration of peptides is low at the start of extraction.

''Column-switching'' protocols have been employed where analytes in crude mixtures need to be analyzed directly by MS. Such a protocol avoids SPE preparation by relying on interaction of the analyte with the stationary phase while most endogenous components are washed to waste. Selective chromatographic conditions retain the analyte until sufficiently clean and then pneumatically switched valves redirect flow from waste to MS for detection. Such techniques have been demonstrated for the analysis LSD analogs and metabolites in urine.[36,37] They allow clean-up with no precolumn sample preparation and direct quantitation by MS methods.

When coupled with HPLC separations, the ionization technique of choice for charged analytes such as peptides is ESI. However, the presence of alkali salts and other nonvolatile compounds in a physiological sample degrades sensitivity by competing efficiently with the analyte for available ESI current. Thus, it is important to remove as many of the nonanalyte components as possible prior to ESI/MS analysis. For MS detection with ESI, clean-up is necessary because the salts and urea present in urine decrease MS performance by physically occluding the atmospheric inlet and coating the lenses used to complete desolvation and then focus ions. An additional problem with salt in a sample is that alkali metals such as sodium are efficiently bound to carboxylic acid moieties, decreasing the relative amount of $[\text{peptide} + \text{H}]^+$ available for detection by single or multiple ion monitoring of a narrow m/z range around the $[\text{peptide} + \text{H}]^+$ value. With such orthogonal techniques as ion exchange and HPLC coupled on-line to MS it is important that the ion exchange cycle be followed by thorough rinsing to avoid such problems as ion adduction to analytes. The following study demonstrates the use of a ''column-switching'' chromatography system for automated, on-line detection of peptides in urine by ESI/MS.

5.2 Tandem Liquid Chromatography/Mass Spectrometry Quantitation of Peptides in Urine

Prior to use, refrigerated urine is treated with trifluoroacetic acid (TFA) to give a final concentration of 1% and a pH of approximately 3.0. Excess endogenous materials precipitated by TFA are removed by centrifugation at 3000 rpm for 30 min. The supernatant from acidified urine is filtered through 0.2-μm Anodisc. For ion-exchange HPLC, a 1 M potassium phosphate stock solution filtered through a 0.2-μm Anodisc filter is used to prepare mobile phases A (75 mM) and B (700 mM) by dilution. Before final dilution with HPLC-grade water, acetonitrile is added to A and B so that the final concentration is 7.5% and the pH is adjusted to 3.5 with 85% phosphoric acid. For reversed-phase HPLC, mobile phases C and D contain 0.05% TFA with 2% and 60% methanol, respectively. Solutions of IRI-695 (*N*-acetyl-L-arginyl-L-prolyl-L-aspartyl-*NH*-isobutyl) are prepared at 0, 2, 10, 100, 500, and 1000 ng mL^{-1} in water or urine and each contains 400 ng mL^{-1} of IRI-959 (*N*-acetyl-L-arginyl-L-prolyl-L-aspartyl-*NH*-isopentyl).

A diagram of the column-switching apparatus is shown in Figure 2. Pump one (P1) is a Waters Model 616 (Division of Millipore Corp., Milford, MA, USA) capable of delivering four different mobile phases; pump two (P2) consists of two Shimadzu Model LC-10AD units linked to perform a linear gradient; and pump three (P3) is a single Shimadzu Model LC-10AD. Additional instruments include a Model 717 autosampler, a Model 600S controller, and two Model 486 tunable absorbance UV detectors. Both UV detectors are connected to Hewlett-Packard 3395 recording integrators (Palo Alto, CA, USA). Two Rheodyne (Cotati, CA, USA) high-pressure automated six-port switching valves are used with pneumatic actuators engaged at 80 psi. The HPLC columns are as follows: for cation exchange, a Spherisorb Phase Sep SCX, 250 mm × 4.6 mm i.d. column with 5-μm particles (Norwalk, CT); for trapping prior to reversed-phase HPLC, a YMC S3 ODS, C18, 50 mm × 4 mm i.d. column with 3-μm particles (Wilmington, NC, USA); and for analytical reversed-phase separation, a YMC Basic S5, 250 mm × 2 mm i.d. column with 5-μm particles. All columns are kept at 35 °C inside a Shimadzu CTO-10A column heater.

The mass spectrometer is operated at unit resolution in multiple ion monitoring mode, scanning continuously during tandem liquid chromatography/mass spectrometry (LC/LC/MS). The range scanned for analyte (IRI-695; $[\text{M} + \text{H}]^+ = 485$) and internal standard (IRI-959; $[\text{M} + \text{H}]^+ = 499$) is set at $[\text{M} + \text{H}]^+ \pm 1.0$ amu. One complete scan of the $[\text{M} + \text{H}]^+$ value for both peptides took 2 s. Chromatographic separations are monitored by UV absorption at 210 nm after the ion-exchange column

Figure 2 Solvent flow diagram for the four cycles of orthogonal ion-exchange chromatography/reversed-phase HPLC (LC/LC/MS) used to clean up peptides in raw urine prior to on-line analysis by ESI/MS. MPA–MPD refer to mobile phases A–D.

and after the analytical column. Figure 2 shows the four stages of one LC/LC/MS cycle. Pump P1 maintains flow through the ion-exchange column at 1 mL min^{-1} through all four stages and delivers mobile phases A, B and C. Pumps P2 and P3 deliver mobile phases C and D at 0.25 mL min^{-1}. Pump P3 provides a constant flow of mobile phase D to the mass spectrometer with a post-column splitter sending one-third of that to the ESI source and two-thirds to the second UV detector.

5.3 Discussion

This LC/LC/MS method consists of four cycles (Figure 2). The only sample preparation prior to injection onto the cation-exchange column involved acidification of raw urine followed by centrifugation. This ensures that peptides are at an acidic pH sufficient for cation exchange to work efficiently and removes endogenous components that flocculate during refrigeration. During cycle 1 (Figure 2), peptides in urine are loaded on a cation-exchange column and washed just as during SPE preparation. After washing the column to remove as much endogenous material as possible, the peptides are transferred directly by a gradient of increasing potassium phosphate concentration to a reversed-phase trapping column. The trapping column and analytical column avoid contamination by most of the endogenous urinary waste because the valve between the cation-exchange and trapping column does not flow directly toward the trapping column until immediately prior to gradient elution of the peptides.

Valve switching times were determined by monitoring UV absorbance of peptides after injecting a 0.1 mg mL^{-1} standard solution. The first UV detector, located after the cation-exchange column (Figure 2), allows valve switching times to be optimized so that most UV-absorbing material goes to waste rather than to the trapping column. Based on the area under the curve, 90% of the UV-absorbing material goes to waste prior to elution of the peptides. The isopentyl group of IRI-959 ensures chromatographic resolution from IRI-695, which contains an isobutyl group instead of the isopentyl group. Peptides IRI-695 and IRI-959 were resolved chromatographically on both the cation-exchange and reversed-phase columns.

An initial concern with ESI/MS detection was the high potassium phosphate concentration needed to carry out ion exchange. Any peptide adducts would reduce the limit of detection of the method by reducing the $[M + H]^+$ species available for detection. In solution, peptides readily form adducts with potassium and/or phosphate ions that are easily observed by ESI/MS. However, neither potassium nor phosphate adducts to the peptides were observed by ESI/MS. One other concern prior to the study was the high content of urea in urine. It was expected

Figure 3 Linear regression used to quantitate peptides in urine. To generate the curve an internal standard (IRI-959) was spiked at a constant amount and the concentration of the analyte (IRI-695) was varied from 2 to 1000 ng.

that the chromatography would be degraded and the atmospheric pressure inlet clogged because the average concentration of urea in urine is 330 mM. To test whether or not urea would have an effect on peptide recovery and cause the mentioned physical problems, IRI-695 and IRI-959 were spiked into a 330 mM urea solution and analyzed by LC/LC/MS. This high concentration of urea alone did not change the recovery of peptides, nor did it cause any other obvious physical problems with equipment, which suggests that most of the urea was removed during the cation-exchange cycle (data not shown).

Ruggedness of the columns was determined by multiple urine injections. Approximately 100 urine injections were done without any change of HPLC columns. Inclusion of the internal standard in each sample provided a measure of column performance. Any change in chromatographic resolution could be noted and changes made. However, during the course of developing this method the reproducibility of retention times proved the method to be rugged. The limit of detection for IRI-695 in water was 2 ng mL^{-1} and in urine 10 ng mL^{-1}. Performance of the ESI-heated capillary used in desolvation of analyte did not degrade over the course of 100 analyses. Detection of IRI-695 in urine by LC/LC/MS was linear from 10 to 1000 ng mL^{-1} (Figure 3) and sensitive, with a limit of detection of 10 ng mL^{-1}. The LC/ESI/MS process is completely automated and chromatographic fidelity is maintained after over 100 separations without a change of column.

6 CHIRAL ANALYSIS

6.1 Chiral Amino Acid Analysis

Characterization of peptides for an investigational new drug or new drug application submission to the FDA

requires that all impurities above 0.1% level be identified. It is expected that most impurities will be related to the product chemically. For peptide drugs this means that the related substances may be oxidized forms, truncated forms resulting from degradation of the parent peptide, the parent peptide with protecting groups intact from the synthesis or simply a chiral impurity. Using reversed-phase HPLC, most related substances can be separated from the parent peptide and purified for characterization. In an automated setting, impurities might be characterized on-line with some sort of data-dependent MS/MS ICL procedure. If this is not practical because of limited sample, then scale-up for purification is necessary.

Related substances that are isobaric with the peptide drug are likely to be stereoisomers where one or more amino acid is in the D-amino acid configuration rather than the bioactive L-amino acid form. Substitution of a D-amino acid for an L-amino acid may result in a biologically inactive drug or, worse, impart some sort of toxic property not present in the all-L-amino acid peptide. Thus, chiral analysis of a peptide drug and any related substances is an important part of the overall characterization process before submission to the FDA. Methods that provide rapid and accurate assessment of chiral purity have been developed and will be reviewed in sections 6 and 7.[38,39]

6.2 Liquid Chromatography/Mass Spectrometry Chiral Purity

An LC/MS method that allows fast determination of the chiral purity of a peptide is described that involves hydrolysis in deuterium-enriched HCl (DCl)–deuterium-enriched acetic acid (DOAc) followed by derivatization with a chiral reagent (Scheme 1) to create diastereomers that can be separated and quantitated by LC/MS. During peptide hydrolysis the ratio of D-/L-amino acids present in the original peptide can change significantly by acid racemization through an enol intermediate.[38] Peptide hydrolysis in deuterated solvents labels amino acids that racemize during hydrolysis with one deuterium at the chiral center. Racemized amino acids, labeled with deuterium, can be distinguished from non-racemized amino acids by MS because of the increase in molecular weight by one mass unit. Labeling with 1-fluoro-2,4-dinitrophenyl-5-L-alanine (FDAA) allows the five L-amino acids found in a control peptide thymopentin and all possible D-amino acid pairs to be separated in one chromatographic experiment on a conventional reversed-phase column.[38] All peptides were hydrolyzed for 18 h at 130 °C in 1:1 HCl–HOAc or DCl–DOAc. Hydrolyzed peptides were lyophilized and then dissolved in 400 μL of water. To this was added 100 μL of 1 N $NaHCO_3$ and then 200 μL of 38.7 mM FDAA in acetone. The solution was vortexed and incubated at 40 °C for 1 h. Reactions were quenched by 50 μL of 2 N HCl. For LC/MS analysis, samples were diluted 1:10 with solvent A described below. Amino acids labeled with FDAA are referred to as 1-fluoro-2,4-dinitrophenyl-5-L-alanine-labeled or DNPA-amino acids in the text.

1-Fluoro-2,4-dinitrophenyl-5-L-alanine amide

1-L-Alanine-2,4-dinitrophenyl-5-L-alanine amide

Scheme 1 Derivatization of an amino acid with FDAA amide after peptide/protein acid hydrolysis. The derivatization reaction produces a diastereomer, as in this example with alanine, that becomes 1-L-alanine-2,4-dinitrophenyl-5-L-alanine amide or DNPA-alanine.

HPLC separation was by linear gradient using a YMC basic 2.0 × 250-mm column with post-column flow splitting. Two-thirds of the flow was split for UV detection at 340 nm and one-third was split for MS detection. Solvent A was 0.05% TFA, 1.0% methanol and 5.0% acetonitrile and solvent B was 0.05% TFA, 1.0% methanol and 60.0% acetonitrile. Alternatively, a 10 mM ammonium formate (pH 5.2) solvent system was used that was prepared with the same methanol and acetonitrile concentrations as per solvents A and B above but without the TFA. This was done by bringing solvents A and B to volume (1.0 L total each) using 10 mM ammonium formate instead of water. The flow rate at the pump was 0.25 mL min^{-1} and in 20 min the gradient went from initial conditions of 80%A–20%B to 20%A–80%B. For LC/MS, flow from the column was 0.083 mL min^{-1}, such that with the coaxial sheath (methanol) the total flow was 0.183 mL min^{-1} and +3.0 kV was applied for ESI. When a single amino acid was suspected of being in the D-amino acid form then the mass spectrometer was operated at unit resolution and scanned ±5.0 units around the ion of interest. To increase sensitivity at unit resolution, only one ion of interest was scanned per LC/MS run. Alternatively, single ion monitoring (e.g. for $[\text{DNPA-lysine} + H]^+ = 393$)

Figure 4 Chromatographic separation of the 10 D- and L-amino acid diastereomers possible from hydrolysis of the peptide Arg-Lys-Asp-Val-Tyr.

was also carried out to observe simultaneously each of the five amino acids in thymopentin. Controls using D- and L-amino acids found in thymopentin were used to establish order of elution. The relative chiral purity of each D-/L-amino acid pair was calculated from the integrated area of extracted ion chromatograms (Figure 4).

6.3 Discussion

The method has been used to establish the chiral purity of a thymopentin-related substance. The unknown was originally present at less than 0.1% level relative to thymopentin. From proton nuclear magnetic resonance data it was suspected that the impurity contained D-Asp or D-Val and possessed a second lysine residue. Three standards were synthesized for comparison: Arg-Lys-Lys-Asp-Val-Tyr; Arg-Lys-Lys-D-Asp-Val-Tyr; and Arg-Lys-Lys-Asp-D-Val-Tyr. After processing through the above protocol, it was concluded that the impurity was composed of only L-amino acids. The impurity then had to be isolated for sequence analysis by MS and Edman chemistry. It was found to have the sequence Arg-Lys-Lys-Asp-Val-Tyr. Note that Figure 4 shows the separation of all D- and L-amino acids involved in this study. A more comprehensive study showed that all L-amino acids and their D-amino acid pairs could be separated in a single LC/MS run.[38]

7 COMPARATIVE TANDEM MASS SPECTROMETRY

7.1 Background on Collision-induced Dissociation of Peptides

Interpretative CID routines like SEQUEST compare observed CID spectra of peptides to artificial spectra of peptides found in sequence databases and generate a list of most likely matches. Such routines work very well, but lack the ability to incorporate chemical information found in the peptide sequence; the artificial CID spectrum created by a computer routine will be a series of m/z values of equal intensity. An objective comparison of the tendency of a series of related peptides to generate specific fragments can be used to yield information useful in screening peptide drugs for specific impurities. This section will provide an example of such a comparative analysis.

Before preceding it is necessary to review briefly the fragment ion nomenclature used by mass spectrometrists to describe fragment ions used for sequence analysis. For sequence analysis, proteins are processed by proteolysis to peptides, which are then analyzed easily by electrospray ionization/tandem mass spectrometry (ESI/MS/MS). Trypsin is often used because proteins tend to have numerous cleavage sites for trypsin (i.e. Lys and Arg), but also because peptides produced by tryptic digestion of a protein have either lysine or arginine at the carboxyl-terminus and thus with a charge fixed at the carboxyl-terminus will produce a nearly complete series of y-ion fragments. Peptide fragments that retain charge on the carboxyl portion are termed y-ions and on the amino-terminus b-ions (Figure 5a).[40] An example of how fragment ions are calculated for the pentapeptide Arg-Lys-Asp-Val-Tyr is shown in Figure 5(b).

Data accumulated over the years allow certain predictions to be made about the CID spectrum of a peptide based on the amino acid sequence (i.e. the

Figure 5 (a) Peptide fragment ion nomenclature as suggested by Roepstorff and Fohlman.[40] (b) Example of calculating b- and y-ion fragments for a peptide (Tp-5 or thymopentin) from nominal residue masses.

Figure 6 Low-energy MS/MS spectra of the $[M + H]^+$ ions for the peptides RKDVY (Arg-Lys-Asp-Val-Tyr) (a) and RKEVY (Arg-Lys-Glu-Val-Tyr) (b) acquired by ESI on a TQ mass spectrometer. Note the intense b3 ion formation in (a) relative to (b).

peptide chemistry). For instance, a peptide with the amino acid proline in the sequence will, because of the basicity of the proline imide bond being greater than that for any of the amide bonds, fragment preferentially at the amino-terminal side of proline (i.e. at the imide bond).[41] Peptides that contain aspartic acid tend to fragment on the carboxyl side of aspartic acid.[42] It is thought that this happens because of the ability of the aspartic acid side chain to form a stable five-membered ring with the adjacent amide bond and thus influence departure of the carboxyl fragment. Glutamic acid, which would form a less-favored six-membered ring, does not show the same tendency (Figure 6).[42] Although the interpretation of such chemical information remains largely a difficult process limited to skilled analysts, comparative information can be used to analyze related peptides for slight chemical differences such as presented by changes at a chiral center.[43]

An alternative to the LC/MS chiral method presented above was devised using comparative MS/MS of synthetic standards.[39] Just as in section 6 above, it was of interest to know when a D-amino acid isomer of the peptide Arg-Lys-Asp-Val-Tyr (RKDVY) appeared during stability studies or as a result of production procedures. The study used the series of peptides based on the peptide RKDVY, where each L-amino acid was replaced with a D-amino acid such that there were six peptides for comparison. The study compared the CID of each of six peptides using electrospray ionization/triple quadrupole tandem mass spectrometry (ESI/TQ/MS/MS) and electrospray ionization/ion trap tandem mass spectrometry (ESI/IT/MS/MS) and looked at both the 1+ and 2+ ions for each of the peptides.[39] It was shown that peptides in this isomeric series produced fragments that could be correlated with unique structural features of individual peptides.

7.2 Chiral Analysis of Peptides by Tandem Mass Spectrometry

CID spectra of the following peptide 1+ and 2+ ions were compared: Arg-Lys-Asp-Val-Tyr, D-Arg-Lys-Asp-Val-Tyr, Arg-D-Lys-Asp-Val-Tyr, Arg-Lys-D-Asp-Val-Tyr, Arg-Lys-Asp-D-Val-Tyr and Arg-Lys-Asp-Val-D-Tyr. All peptides ($1.5\,\text{pmol}\,\mu\text{L}^{-1}$) were introduced into an ESI source by direct infusion at $3\,\mu\text{L}\,\text{min}^{-1}$ in an acidic solution. Low-energy CID spectra were obtained on a Finnigan tsq 7000 TQ mass spectrometer and a Finnigan lcq IT mass spectrometer (San Jose, CA). For comparison, CID spectra were averaged for 1 min and collision energies were optimized for one of four sets of experiments: triple quadrupole collision-induced dissociation (TQ/CID) of 1+ ion ($680\,m/z$), TQ/CID of 2+ ion ($340\,m/z$), ion trap collision-induced dissociation (IT/CID) of 1+ ion and IT/CID of 2+ ion. Specifically the fragment ions b3 (400 amu) and b4 (499 amu) were compared. For graphical comparison, the ratio of the observed intensity of b3/b4 ions in each isomer was calculated and all values normalized to the same ratio for the all-L-amino acid peptide. This type of data analysis allows an unbiased assessment of the tendency of a given isomer to form the fragment ions b3 and b4. As seen in the following discussion, when bar graphs of such data are used for comparison an objective analysis can be done even by a novice.

7.3 Discussion

Some general trends are apparent when comparing the IT and TQ/CID of peptides. The most obvious is the reduction in complexity in the IT data. Fewer fragment ions are observed with the IT/CID of a 1+ ion (Figure 7a, c) than with the TQ (Figure 7b, d). This is likely due

Figure 7 Low-energy MS/MS spectra of the $[M + H]^+$ ions for the peptide Arg-Lys-Asp-Val-Tyr (all-L-thymopentin or all-L-TP-5) in an IT (a) and TQ (b) and for the peptide Arg-Lys-D-Asp-Val-Tyr in an IT (c) and TQ (d).

in part to temporal differences between CID in an IT and a TQ. The IT acquires spectra about 10 times faster than the TQ. The TQ, being a relatively slow (1–2 s per scan) scanning instrument, allows more time for secondary fragmentation of b- and y-ions than the IT. It is often the case that many of the fragment ions present in the MS/MS spectrum of a peptide from a TQ instrument will be difficult to interpret, whereas most of the fragment ions for the same peptide can be assigned in an IT. A disadvantage of the IT data is that there are no immonium ions present.[44] Peptide ions will fragment during CID to constituent amino acids that consist of a basic unit where an immonium group bears the charge and the amino acid side chain is retained, providing a unique mass for each of the 21 possible amino acids except leucine/isoleucine, which are isobaric. Immonium ions are diagnostic of the amino acids present in a peptide.

The CID of the 1+ ions, but not the 2+ ions, showed marked differences between isomers. The trend for the 1+ ions is shown in Figure 8. The lack of a trend in the fragments from the 2+ ions is likely to be due to Coulombic repulsion. A peptide with two charges requires less energy for fragmentation than a peptide with only one charge due to Coulombic repulsion. The repulsion between two charges on one peptide molecule lowers the energy barrier to fragment ion formation. This effect likely prevents observation of any subtle differences between isomers that are apparent with the 1+ ions. Such subtle differences between isomers are observed in the 1+ ion series on both instruments.

Both instruments showed differences in fragmentation when D-amino acids were substituted for L-amino acids near positions 3 and 4 of RKDVY, but the IT 1+ ion data showed a more prevalent trend than the TQ 1+ ion data. Substitution of D-amino acids near the amino-

Figure 8 Comparative analysis of the tendency to form the b3 ion versus the b4 ion in the isomeric series for peptide Arg-Lys-Asp-Val-Tyr (TP-5 or thymopentin) in an IT (a) and TQ (b). The b3/b4 ratio of ion intensity for each D-amino acid isomer of TP-5 is normalized to that observed for TP-5.

and carboxyl-terminii did not affect fragmentation of the b3/b4 ratio. This is expected, based on the tendency of this given peptide sequence (i.e. chemistry) to form intense b3 and b4 ions relative to all the other possibilities. The most obvious trend is in the IT 1+ ion data (Figure 8a) where the D-Val-thymopentin isomer was the most likely to form the b3 ion relative to the b4. The D-Val-thymopentin isomer likely decreases the energy barrier to the formation of this b3 fragmentation pathway via a specific steric constraint that promotes the formation of the putative five-membered ring between the aspartic acid side chain and the ''b3'' amide bond (Figure 8a). Recall that in an all-L-amino acid peptide each amino acid in the sequence points away from the backbone in an alternating fashion. As soon as one D-amino acid is introduced, then the adjacent L- and D-amino acids will have side chains on the same side of the amide bond backbone rather than the normal where side chains project to one side or the other in an alternating fashion down the backbone. Interestingly, the 1+ ion CID data from the TQ does not show the same strong trend toward the D-Val-isomer (Figure 8b). The D-Val isomer is still the most likely to produce the strongest b3/b4 ion ratio, but now the series dips at the D-Lys isomer. In this case the D-Lys isomer must interfere with the formation of the five-membered ring by the L-Asp side chain and the ''b3'' amide bond. Given the longer time frame of the CID experiment in the TQ the D-Lys isomer must allow stabilization of a structure that prevents facile cleavage of the b3 amide bond. Whatever the physicochemical explanation, such graphical displays of data allow even the novice to find trends. In this case comparative MS/MS analysis on either instrument shows a definite influence from the substitution of an L-amino acid for a D-amino acid. As such, these comparative analyses could be used as a less labor-intensive method to screen impurities in libraries than the chiral analysis presented in section 6. Unless there is a compelling reason to use TQ/MS, then IT/MS analysis would offer the advantages of faster scans, lower instrument start-up costs and less complex CID data to interpret.

8 NONCONVENTIONAL MASS SPECTROMETRY

8.1 Noncovalent Complex Analysis

One area of MS that is nonconventional but appropriate for biological studies is the study of noncovalent complexes. In the past 10 years a number of articles have been published describing this research.[6] Basic to these studies is the use of soft ionization techniques like ESI to transfer noncovalent complexes from solution to the gas phase. Argument continues about whether or not the ionization process significantly perturbs the system under study. However, a number of studies would indicate that when proper controls using techniques such as nuclear magnetic resonance and circular dichroism are conducted, then the results can be trusted. In fact, one of the earliest studies showed that the dissociation constant K_d for a series of enzyme inhibitors had the same relative affinities in the gas phase as in solution.[45] Thermal denaturation of RNAse S in the gas phase also correlated with the change in enthalpy (ΔH) of dissociation measured by traditional calorimetry.[46] As a last application an example will be presented showing that the thermal denaturation of DNA measured in a manner analogous to that for RNAse S exhibits a melting temperature T_m close to that shown by circular dichroism.

Guanine-rich DNA can be found in the telomeric region of certain chromosomes.[47] When removed from the chromosome and analyzed as small oligonucleotides these guanine-rich sequences form quadruple-stranded complexes in the presence of cations such as K^+, Ca^{2+}

and Na^+, but dissociate into single-stranded DNA in the absence of cations. Proton nuclear magnetic resonance, circular dichroism and electrophoresis have been used to study the cation-dependent thermal stability of quadruplex DNA. Also, it has been shown previously that these quadruplex–cation structures and more common duplex structures can be transferred intact into the gas phase.[48,49] The following example shows that on-line thermal denaturation of the quadruplex–cation structures can be used to estimate the T_m of such non-covalent structures by ESI/MS.

8.2 Thermal Denaturation of Noncovalent Complexes

Liquid-phase thermal denaturation was conducted in 60 cm of an 80-cm length of 50-μm i.d. × 180-μm o.d. fused-silica capillary wrapped in heating tape, with segments of about 8 cm at the ESI sources and 12 cm at the syringe remaining unheated. Temperature was measured with a thermal couple placed inside the heating tape and next to the fused-silica capillary. For thermal denaturation studies the capillary was filled with sample and incubated at a given temperature for 10 min prior to acquiring ESI data. After the thermal equilibration period the syringe pump was turned on and the sample infused at 0.5 μL min^{-1}. The thermally equilibrated sample was pushed out of the syringe using distilled, deionized water. The synthetic oligomer for the study had the sequence d(CGCGGGGGCG). The single-stranded oligomer was prepared for ESI/MS by HPLC purification to remove low-molecular-weight impurities and residual salt. Quadruplex-DNA was prepared in the presence of 10 mM sodium phosphate (pH 7.6) containing 0.1 mM ethylenediaminetetraacetic acid (EDTA) from single-stranded d(CGCGGGGGCG) according to established protocols.[50]

For MS a home-built SQ instrument was used that was assembled from Extrel components and consisted of a nozzle-skimmer atmospheric pressure inlet followed by an RF-only quadrupole surrounded by a cryopumping surface.[44] The front plate was held at ambient temperature and the lens was at 1.0 kV. A counter-current stream of nitrogen gas at ambient room temperature was used to assist desolvation and a co-axial stream of SF_6 within the ESI source prevented discharge from the aqueous solutions. ESI was carried out in negative ion mode.

8.3 Discussion

At room temperature in 10 mM sodium phosphate (pH 7.6) and 0.1 mM EDTA, ions corresponding to both single-stranded d(CGCGGGGGCG) (i.e. G4) and quadruplex G4 (i.e. $(G4)_4$) were observed at a low nozzle-skimmer bias of −150 V (Figure 9a): so-called

Figure 9 Thermal denaturation of quadruplex DNA ($(G4)_4$) in solution at room temperature and low nozzle-skimmer bias (a) analyzed by negative ion ESI/MS. The $(G4)_4$ DNA dissociates at high temperature (b) or high nozzle-skimmer bias (c) into single-stranded DNA (G4).

noncovalent friendly conditions on this particular instrument. The $(G4)_4$ species could be converted largely to the single-stranded G4 by raising the nozzle-skimmer bias to −250 V (Figure 9b) or by raising the solution temperature to 90 °C (Figure 9c). This simple result agrees with circular dichroism studies carried out under identical conditions of ionic strength and ionic species present, which showed that the quadruplex DNA had a T_m of 90 °C. A study of a related quadruplex $[d(CGCGGGGCG)]_4$ showed that it had a T_m of approximately 80 °C. This measurement also agreed with circular dichroism studies and the chemical intuition that one less guanine would lower thermal stability.[51] Although such studies are decidedly difficult to carry out, a number of pharmaceutical companies have made a significant investment in using ESI/MS analysis of noncovalent complexes to screen ligand libraries as a guide prior to further drug development.

9 CONCLUSIONS

As can be seen by the diversity of applications provided, the use of MS in the field of pharmaceutical sciences is vast and a single chapter cannot adequately address all the issues at hand. It covers fields as diverse as protein chemistry, combinatorial chemistry, and clinical chemistry. This article sought to address some of the more common uses of MS in pharmaceutical sciences by presenting novel approaches to quantitation of peptides in urine, chiral analysis of peptides, comparative MS/MS and thermal stability of noncovalent complexes. Each of these single areas constitutes a field of research in itself. So it is hoped that the reader gains enough insight from the discussions to have a basic understanding of each field of study presented here.

The future of MS in pharmaceutical sciences promises to include more often the use of Fourier transform ion cyclotron resonance/mass spectrometry (FTICR/MS). An excellent review of this technique was published recently and so the fundamentals of FTICR/MS operation will be left for the reader's initiative.[52] The reason why FTICR/MS is likely to become so important are fourfold: high resolution (e.g. 1 000 000 @ 1000 amu as $m/\Delta m$ at 50% peak height); high mass accuracy (at least 1 ppm @ 1000 amu; i.e. for 1 ppm @ 1000 amu the mass can be measured accurately to the thousandth place as 1000.001 amu); high sensitivity (zepto- to attomoles for small molecules); and broad dynamic range; all these advantages are combined in one instrument. Additionally, all of these benefits can be carried out on-line with HPLC or capillary electrophoresis and with either ESI or MALDI ionization. The possibility to make accurate m/z measurements to 0.1 ppm (@ 1000 amu) should make it feasible to identify proteins in sequence databases based on the accurate mass tag provided by a single peptide molecular weight.[53] This advantage will allow the identification of analytes in defined libraries without time-consuming MS/MS procedures and promises to increase significantly the rate at which samples can be screened.[54]

ACKNOWLEDGMENTS

DRG acknowledges the following people for scientific counsel and inspiration over the past 10 years, during which much of this work was done: Richard B. van Breemen, Richard D. Smith, Charles G. Edmonds, Rachel Ogorzalek Loo, Harold R. Udseth, John W. Tolan, Jeffery Shabanowitz, John R. Yates, III, Ruedolf H. Aebersold and Donna M. Goodlett. Nuclear magnetic resonance (NMR) spectroscopy is an extremely powerful tool for the detection, identification and quantification of drugs and related substances. The whole range of one-dimensional (1-D) and two-dimensional (2-D) NMR techniques is available for performing the required analyses. These NMR methods may be used for routine purposes, such as the confirmation of the identity of the drug or quantification of the amount of drug substance present in a formulation. However, the area where NMR stands out as an analytical tool is in the identification of unknown compounds such as metabolites or drug degradation products. NMR is also used for impurity profiling or determination of the drug's optical purity.

Although NMR has been used for many years to analyze drugs, even the most modern spectrometers lack the sensitivity obtainable by other techniques such as mass spectrometry (MS) or high-performance liquid chromatography (HPLC). However, NMR is a nondestructive technique which provides essential structural information that cannot easily be obtained from these other methods. Recent advances in technology have allowed the interfacing of NMR instruments with other equipment such as HPLC devices to provide even more robust analytical methodology.

1 INTRODUCTION

The nuclei of atoms with an odd number of protons, neutrons, or both, have an intrinsic nuclear *spin*. The spinning of charged particles – the circulation of charges – produces a magnetic moment along the axis of spin. The simplest nucleus possessing a spin is the proton – the nucleus of the hydrogen atom. If hydrogen atoms are placed in an external magnetic field, their magnetic moments, according to quantum mechanics, will become aligned in one of two ways – with or against the external field. For hydrogen, the more stable alignment is with the field and energy must be absorbed to ''flip'' the proton over to the less stable alignment against the field. The amount of energy needed to flip the proton depends on the strength of the external field: the stronger the field, the greater the energy required to produce the flip. The energy required corresponds to electromagnetic radiation in the radiofrequency (RF) range. The observation frequency is given by Equation (1)

$$\nu = \frac{\gamma H_0}{2\pi} \tag{1}$$

where ν = frequency, in cycles per second; γ = a nuclear constant (the gyromagnetic ratio) and H_0 = strength of the static magnetic field, in tesla. When the nucleus is irradiated at the proper frequency, absorption occurs, followed by the nuclei re-emitting the RF radiation to return to the lower energy state. This process gives rise to a signal and the spectrum arising from this signal is called an NMR spectrum. The frequency at which a nucleus absorbs depends on the magnetic field that it *feels*, and this *effective* field strength is not exactly the same as the *applied* field strength. The effective field strength at each nucleus depends on its environment – the electron density, closeness of other nuclei, etc. – and hence in each case a slightly different applied frequency is required in order for absorption to take place. Thus each different nucleus will give rise to its own signal.

There are two basic NMR spectrometer designs – continuous wave (CW), and pulsed or Fourier transform

(FT). CW spectrometers have low-field water-cooled electromagnets which consume large amounts of electricity. The newer Fourier transform nuclear magnetic resonance (FTNMR) spectrometers use liquid-helium-cooled superconducting magnets which consume very little electrical power, but require relatively expensive cryogens (liquid nitrogen and liquid helium) to keep them working. Although CW spectrometers are perfectly suitable for many routine applications, they have largely been replaced by the higher-field pulsed FTNMR instruments.

Because the energy difference between the nuclei aligned with and against the field is small, the number of nuclei in each spin state are almost equal. There is, however, a slight excess of spins in the more stable alignment (of the order of 1 in 10^5 for protons at 200 MHz). It is the signal from this excess which gives rise to the NMR signal, thus explaining the relative insensitivity of this technique. However, over the last 20 years, the field strength (and thus sensitivity) has grown by leaps and bounds. Even the more routine modern instruments (300–500 MHz) are capable of producing good quality proton NMR spectra with microgram amounts of small drugs and related compounds. Lower field spectrometers are useful for acquiring routine spectra from smaller molecules where sample quantity is not limited. Higher-field magnets (currently up to 18.8 T, with a proton frequency of 800 MHz) are required for more demanding research applications.

When regulatory laboratories are performing analyses of pharmaceutical products, the analytical techniques used must meet a number of strict criteria. Besides being sufficiently sensitive, they must be highly selective, reproducible and suitable to give qualitative and, in many cases, quantitative analyses. Other desirable features for more routine pharmaceutical methods include that they require the minimum amount of sample pretreatment and that they be able to handle mixtures of substances without prior separation. As will be seen from the following discussion, NMR spectroscopy meets all these requirements and is becoming more and more important for identification of unknown substances, as well as for routine analyses, in many pharmaceutical laboratories throughout the world.

Organic compounds, including pharmaceuticals, are composed of relatively few chemical elements (hydrogen, carbon, oxygen, nitrogen, and phosphorus, as well as the halogens and sometimes metals). Each of these elements has one or more isotopes that may be detected by NMR experiments. However, due to low natural abundance and/or low relative sensitivity of the nuclei, many of these elements are not routinely studied. Those that are commonly studied include hydrogen (^{1}H), carbon (^{13}C), fluorine (^{19}F) and phosphorus (^{31}P). In order to study the structure of larger macromolecules (proteins, for example), it is usually necessary to enrich (i.e. label) the samples with ^{13}C, ^{15}N and sometimes ^{2}H (see section 2.3.2.5).

2 ANALYSIS OF DRUGS

2.1 Sample Types

The most important role NMR plays in pharmaceutical analysis is its use in elucidation and/or confirmation of structures for drug-related substances. This would include the drugs themselves, either as raw materials or in formulations. NMR has also been used extensively to study drug impurities including solvents, synthetic precursors, synthetic intermediates, and decomposition products. In the case of natural products NMR may be used to determine the identity of co-extractives. Another key area where NMR has proved to be invaluable is in the study of drug metabolism where it has been used for identification and quantification of many metabolites.

In addition to the high-resolution solution NMR techniques, several other magnetic resonance methodologies are sometimes used in pharmaceutical studies. Solid-state NMR has been used to study polymorphism of drug powders. Micro-imaging NMR may be used to study dissolution of drug tablets. The use of whole-body imaging NMR is a very powerful tool for clinical diagnosis. Extensive discussion of these areas is beyond the scope of this article.

2.2 Sample Preparation

The methods used to prepare the pharmaceutical samples for NMR analyses depend on the source of the sample and the information required. Procedures range from simple dissolution to complex extraction and derivatization reactions which must be done under very stringent conditions.

For the simplest case of ''pure'' drug raw material from a small pharmaceutical, a suitable quantity (usually a few milligrams) of the sample is dissolved in a deuterated NMR solvent. The choice of solvent depends on the solubility and stability of the drug. Commonly used deuterated solvents include chloroform ($CDCl_3$), water (D_2O), dimethylsulfoxide (DMSO-d_6), methanol (CD_3OD) or a mixture of chloroform and methanol ($CDCl_3/CD_3OD$). The amount of sample used depends on the quantity of sample available, the field strength of the spectrometer and the type of NMR experiments to be performed (see section 2.3).

In cases where the pharmaceutical product is a mixture, such as in tablets or elixirs where the drug is mixed with excipients such as sugars or starch, sample preparation

methods depend on the nature of the components. It is often possible to choose a solvent which will dissolve only the drug, leaving the other excipients behind, or to choose two immiscible solvents where the drug will go into one solvent while the excipients go into the other. For example, deuterochloroform will extract many drugs from formulations where the excipients are sugars, since sugars will not dissolve in this solvent but may be taken up in water. In many situations, however, this simple procedure will not work and one must use the chemical characteristics of the drug to separate it from its excipients. Drugs may conveniently be divided into four general categories – acidic, basic, amphoteric and neutral. Each category has different partition coefficients between aqueous and immiscible organic solvents. The hydrogen ion concentration in the aqueous phase, which varies with pH, affects the ionic state or polarity of the drug, depending on the polar substituents present. It is often possible to separate drugs from the different classes from each other or from other organic compounds by proper adjustment of the pH. For example, if the aqueous solution is made acidic, organic solvents may be used to remove acidic and neutral components. On the other hand, if the aqueous phase is made basic, basic and neutral components may be extracted with organic solvents. For amphoteric drugs such as morphine, the pH must be adjusted to its isoelectric point before extraction is possible. At this pH, the drug exists in a nonpolar or nonionized form, making it more soluble in appropriate organic solvents than in water. It is possible to isolate or remove neutral drugs or other organic components from acidic and basic drugs by extracting a basic aqueous solution with an organic solvent, and then washing this solvent with aqueous acid. Only the neutral materials should remain in the organic solvent.

Other procedures such as extraction and derivatization may be required for drugs derived from plant materials. Special precautions may be necessary when the drugs in these materials are not stable under certain conditions – in the presence of acid or base for example. However, because of the complexity of the extracts from most plants, NMR is usually not the method of choice for analyzing these materials.

For drugs where only one optical isomer is allowed in the product, or where there is a limit set on the isomeric content, procedures involving the addition of chiral shift reagents, chiral solvating agents (CSAs), or reaction with chiral derivatizing agents (CDAs) are required (see section 2.3.1.4).

In cases where the study will include the modern ''hyphenated techniques'' (NMR/HPLC, NMR/MS, HPLC/NMR/MS, etc.) the sample preparation may have to be changed to accommodate these other methodologies (see section 2.3.3).

When the pharmaceutical product under study is a protein or polypeptide, considerable effort may be necessary to find optimal conditions (pH, temperature, buffer strength, etc.) at which the sample is soluble, stable and nonaggregating at relatively high concentrations (usually >1 mM).

2.3 Nuclear Magnetic Resonance Experiments

Since the mid-1980s, NMR techniques have advanced dramatically. As the number of experiments increases, many spectroscopists find it difficult to keep up with all the newest procedures available to help solve problems. Most develop a set of experimental techniques which work well for them in obtaining the kind of information they require. What follows is a discussion of the general types of experiments which are most often used in the analyses of pharmaceuticals.

2.3.1 One-dimensional Techniques

2.3.1.1 High-resolution Spectra When most scientists with a passing knowledge of NMR think about this technique, they recall the traditional 1-D high-resolution proton (^{1}H) and carbon (^{13}C) spectra. These spectra are highly informative in the hands of a trained NMR spectroscopist. For those who may not be experts in the field, these spectra may still be used as ''fingerprints'' for comparison with spectra of authentic materials. For this type of work, the use of ^{13}C-NMR spectra is most suitable. ^{1}H-NMR spectra are not as convenient for a number of reasons, the main one being that the appearance of the proton spectra differs significantly when obtained at different field strengths – the higher the field, the more first-order (and thus simpler) the spectra become. At lower field strengths, the ^{1}H-NMR spectra for many drugs consist of broad and uninterpretable envelopes of signals, whereas at higher fields the corresponding spectra contain large numbers of sharp resonances which may be readily assigned using some of the modern techniques discussed below. This may be clearly seen by comparing the 80 MHz and 400 MHz spectra of phencyclidine hydrochloride (Figure 1). On the other hand, ^{13}C spectra look very similar, regardless of the field strength used. The only differences would be for those signals which may only be resolved from each other at higher field strengths.

^{1}H-NMR spectra can give detailed information on the nature of unknown substances. Each different proton in the molecule gives rise to a peak or group of peaks. When there is no overlap in the ^{1}H-NMR spectrum, integration may be used to obtain the relative number of each type of proton. The chemical shift of the protons indicates the environment in which they exist. The majority of protons fall in a range of about

Figure 1 Structure and ^{1}H-NMR spectra for phencyclidine hydrochloride: (a) 80 MHz spectrum; (b) 400 MHz spectrum (blow-ups of the two chemical shift regions illustrate the sharpness of the peaks compared with those of the 80 MHz spectrum in (a)).

10 ppm. The chemical shifts in organic solvents are usually referenced to tetramethylsilane (TMS), which is assigned a value of 0.00 ppm. In aqueous solutions, chemical shifts may be referenced to 2,2-dimethyl-2-silapentane-5-sulfonate (DSS), also at 0.00 ppm. Chemical shifts provide evidence as to whether the protons are aliphatic (0.8–3.0 ppm), olefinic (4.5–6.5 ppm), or aromatic (6.5–8.5 ppm). Protons attached to carbons that are bonded to nitrogen resonate at about 2.0–3.5 ppm, while if the carbon is bound to an oxygen, the protons resonate at about 3.3–4.5 ppm. Aldehyde protons are found around 8.5–10.0 ppm. Complete tables of chemical shifts may be found in most introductory NMR text books. These would include older books such as those by Bible,[1] Abraham,[2] and Emsley et al.,[3] as well as some more recent ones such as that by Günther.[4] A collection of ^{1}H-NMR spectra for a large number of compounds may be

Figure 2 Structure and ^{1}H-NMR spectrum of ketoconazole.

found in the *Aldrich Library*.[5] Examination of the proton spectrum of the drug ketoconazole (Figure 2), shows resonances for many types of protons in the chemical shift ranges indicated.

High-resolution ^{13}C-NMR spectra also provide a great deal of information. The chemical shift range for carbon is more than 200 ppm. As with protons, the chemical shift ranges are indicative of the kind of carbon. Carbon chemical shifts follow basically the same order as protons, with aliphatic carbons being at highest fields, followed by olefinic and then aromatic carbons. Acid and ester carbonyls are at lower fields than aromatic carbons, followed by aldehydes and isolated (nonconjugated) carbonyls at lowest fields. As with protons, tables of typical chemical shifts may be found in most introductory NMR text books which discuss ^{13}C-NMR. These would include older books such as those by Stothers,[6] Wehrli and Wirthlin[7] and Levy and Nelson[8] as well as the newer books mentioned previously.[4,5] Figure 3(a) shows the ^{13}C-NMR spectrum of ketoconazole, with resonances in the ranges indicated.

The number of carbon signals (excluding those from the solvent) usually gives a direct count of the number of chemically distinct carbons in the molecule being studied. Exceptions occur when two or more different carbons have chemical shifts that are too close to be resolved under the conditions of the experiment, when one or more carbons are coupled to another magnetic nucleus that is not decoupled (^{19}F or ^{31}P, for example), or in special circumstances when equilibria between two or more forms of the drug exist in solution (due to hindered rotation, ring inversion, keto–enol equilibria, etc.). In a routine ^{13}C-NMR spectrum, the signals obtained for

Figure 3 ^{13}C-NMR spectra for ketoconazole: (a) normal carbon spectrum (large peaks at 77 ppm are due to the solvent $CDCl_3$); (b) distortionless enhancement by polarization transfer (DEPT) spectrum (CH and CH_3 resonances give positive peaks, CH_2 gives negative peaks, quaternary carbons – including the $CDCl_3$ solvent – do not give any peaks).

quaternary carbons are smaller than those for protonated carbons. It is possible to obtain carbon spectra such that each carbon gives rise to the same size peak by using long relaxation times between scans and taking precautions to eliminate the nuclear Overhauser effect (NOE) (see section 2.3.1.2). When this type of quantitative experiment is performed, one can easily determine if there are unresolved carbon shifts or if any carbons are coupled to any other nuclei, thus enabling the analyst to get an accurate count of the number of carbons in the molecule.

One very important class of 1-D experiment is that which gives a count of the number of protons attached to each carbon. Perhaps the best known of these is DEPT. With a suitable choice of experimental parameters, the ^{13}C spectra obtained will have positive peaks for CH and CH_3 groups, negative peaks for CH_2 groups and no signal for quaternary carbons. Varying the parameters allows one to obtain spectra with only CH or CH_2 or CH_3 carbons appearing. Thus one can readily determine the number of protons attached to every carbon in the compound being studied. The DEPT spectrum for ketoconazole is shown in Figure 3(b). Comparison with the regular carbon spectrum (Figure 3a) illustrates how easy it often is to determine the number of protons attached to each carbon.

Although it is more common to obtain high-resolution spectra for protons and carbons, spectra may be obtained for many other nuclei. Those which are most often studied include ^{15}N, ^{19}F and ^{31}P. Many drugs contain nitrogen, but the low natural abundance and relative insensitivity of the ^{15}N nucleus make it a very difficult atom to study without isotopic labeling. Comparatively large amounts of material are required in order to obtain spectra in a reasonable period of time. Despite this, a number of reports have been published containing ^{15}N chemical shift data for pharmaceuticals. The other two nuclei (^{19}F and ^{31}P) are essentially 100% abundant and are NMR sensitive, but unfortunately they occur in relatively few drugs.

2.3.1.2 Nuclear Overhauser Effect When magnetic nuclei are spatially close to each other, there is a dipolar interaction. If the chemical shift of one of these nuclei is irradiated in order to saturate its spin, any nuclei that are close to it may experience a small change in the size of their signal, referred to as the NOE. For small molecules, such as traditional pharmaceuticals, this effect is usually a signal enhancement. (For larger proteins, the effect may be close to zero or even negative.) The closer the nuclei are to each other, the greater the effect on the signal. The maximum amount of enhancement for small molecules is only a few percent of original size of the signal. Because the strength of the dipolar interaction falls off at a rate which is proportional to

the inverse of the distance raised to the sixth power, nuclei must normally be within about 5 Å of each other to see any observable enhancement. To observe the small signal enhancements, one must obtain a difference spectrum by subtracting a reference spectrum obtained under ''identical'' conditions. (The only difference is that the reference spectrum is obtained while irradiating at a blank part of the spectrum instead of at the chemical shift frequency for one of the nuclei.) When the difference spectrum is plotted, one obtains a large negative peak for the irradiated nucleus and small positive peaks for nuclei experiencing an observable NOE. Thus this procedure often indicates which protons are close to each other in space, thus allowing the spectroscopist to determine the relative stereochemistry in unknown molecules.

2.3.1.3 Lanthanide Shift Reagent Studies The magnetic moments of the unpaired electrons of paramagnetic reagents are capable of producing relatively large chemical shift changes in molecules which are in close proximity. Most paramagnetic reagents are detrimental to the appearance of NMR spectra because they cause severe line-broadening of all the signals. However, a few complexes of the rare earth elements (lanthanides) do cause substantial chemical shift changes without substantial line-broadening on lower-field-strength instruments. The most common of these, referred to as lanthanide shift reagents (LSRs), are composed of complexes of europium, praesodymium or ytterbium with a number of different diketones. The most popular LSRs are complexes with 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dione [$Eu(fod)_3$, $Pr(fod)_3$ and $Yt(fod)_3$] or 2,2,6,6-tetramethylheptane-3,5-dione [$Eu(dmp)_3$, $Pr(dmp)_3$ and $Yt(dmp)_3$].

When a shift reagent is added to a solution of the pharmaceutical, it forms a weak bond to the most basic site in the drug – usually a nitrogen or oxygen. The amount of change in the chemical shift is inversely proportional to the distance between the lanthanide atom and the proton (or carbon). The experimental procedure followed in this type of study is to obtain a spectrum of the drug alone and in the presence of varying amounts of the shift reagent. By following the shifting of the different nuclei, one can determine their relative distances from the reagent, thus providing help in assigning the shifts to the appropriate nuclei. In the case of proton studies, the spreading out of the resonance signals may cause the spectrum to be more first-order and thus easier to interpret.

The amount of line-broadening experienced by nuclei with a given concentration of LSR is directly proportional to the square of the magnetic field strength. Thus, these reagents are not suitable for use on the more modern high-field spectrometers. However, on lower-field instruments they have been used for a wide variety of drugs over the years.

2.3.1.4 Optical Purity Methods Another important class of 1-D experiments is that used to determine the optical isomer content of drugs. For a number of drugs only one isomer should be present in the commercial product. There are three basic types of NMR experiments which may be used to determine the optical purity of pharmaceuticals. The first method to be developed was the use of chiral lanthanide shift reagents (CLSRs). A related method developed later was the use of chiral solvents or CSAs. The final method is the use of CDAs.

The use of LSRs was discussed in section 2.3.1.3. A number of shift reagents have optically active ketone groups. Some of the common CLSRs include complexes with the ligands 3-(trifluoroacetyl)-*d*-camphor [$Eu(tfc)_3$], 3-(heptafluorobutyryl)-*d*-camphor [$Eu(hfc)_3$] and *d*,*d*-dicampholylmethane [$Eu(dcm)_3$]. These materials work in basically the same manner as LSRs, but when these compounds are used they may induce different chemical shift changes for nuclei of optical antipodes. The CLSRs have been used to obtain optical isomer contents for many drugs.

An alternative to CLSRs is the use of one of a series of compounds referred to as chiral solvents or CSAs. These are optically active compounds possessing an aromatic group and a polar functional group such as an amine, alcohol or acid. When a suitable CSA is added to a solution of a drug which also has a polar group, the CSA forms a weak hydrogen bond with the drug. Because the CSA is optically pure, it forms different complexes with each optical antipode of the drug. The aromatic ring current of the CSA is located at different distances from the corresponding nuclei in the drug isomers. This causes the nuclei of the drug to give rise to separate signals for each antipode, thus enabling the optical purity of the drug to be determined. Unlike the CLSRs, no line-broadening occurs when CSAs are used. Higher-field spectrometers provide better separation of signals than lower-field instruments. The structures of some of the more common CSAs are shown below **(1–8)**.

A third method for determining the optical isomer content of drugs is the use of CDAs. As with CSAs, the CDAs usually contain an optical center and an aromatic group. They also contain a functional group (such as an acid chloride) which is capable of reacting and forming a covalent bond with the drug. As with the CSAs, the aromatic group is in different proximity to the nuclei of the drug's antipodes, causing differential shifts in some of the corresponding resonances. In many cases, this difference is sufficient to allow accurate quantification of each isomer. Once again, there is no line-broadening as with CLSRs and the higher-field

spectrometers give better separation than the lower-field instruments.

2.3.2 *Two-dimensional Techniques*

2-D techniques in NMR spectroscopy all involve multiple-pulse experiments containing three basic stages – preparation, evolution and detection. The spectrum that is finally obtained depends on the nature of the preparation and the length of the evolution time. The effects of evolution are not observed directly, but are detected by carrying out a series of experiments in which the evolution time is systematically varied. By following this procedure, two distinct sets of spectroscopic features are obtained – those that influence the magnetization during the evolution time and those that influence the magnetization during the acquisition time. In 1-D NMR Fourier transformation is used to convert the time dependence of the magnetization evolution during the acquisition time into frequency data, while 2-D NMR uses a second Fourier transformation to convert the time dependence of the evolution time into a second frequency.

2.3.2.1 *$^{1}H-^{1}H$ Correlation Spectroscopy Experiments*

One class of 2-D experiments, which may be performed on any modern high-resolution NMR spectrometer, is referred to as correlation spectroscopy (COSY). One of the most common 2-D experiments is $^{1}H-^{1}H$-COSY. The results for this type of experiment are usually displayed as a 2-D contour plot with the 1-D proton spectrum plotted along both the *x*- and *y*-axes. A typical COSY spectrum is shown in Figure 4 for the drug ketoconazole. The contours in this plot indicate the chemical shifts of the protons that are coupled to each other. Thus, to determine which protons are coupled to a particular proton resonance, one simply scans down a column beneath the peak plotted on the *x*-axis. Contours will be found on rows corresponding to peaks plotted on the *y*-axis for protons to which there is detectable coupling. By varying the experimental parameters, one can look for either larger short-range or smaller long-range coupling constants. This experiment allows the spectroscopist to determine which protons are separated from each other by two, three or even four bonds.

2.3.2.2 *$^{13}C-^{13}C$ Correlation Spectroscopy Experiments*

The other homonuclear shift correlation experiment which may be used by spectroscopists is $^{13}C-^{13}C$-COSY. This technique is often referred to in the literature by the acronym INADEQUATE (incredible natural abundance double quantum transfer experiment). This is a very powerful technique which shows all the

Figure 4 $^{1}H-^{1}H$-COSY spectrum of ketoconazole. Contours can be used to determine which protons are coupled to each other by examining the proton spectra plotted along the top and side.

one-bond carbon–carbon connections in the molecule, enabling the complete skeleton of the compound to be determined, except for those parts joined by heteroatoms. However, because of the extremely low sensitivity of this experiment, and the length of time required to accumulate the data, it is seldom used. Instead, spectroscopists use a combination of other techniques to get the same information much more quickly.

2.3.2.3 $^{13}C-^{1}H$ Correlation Spectroscopy Experiments Because of the importance of determining the connections between hydrogens and carbons, a large number of $^{13}C-^{1}H$-COSY experimental techniques have been developed. In the 2-D contour plots for this type of experiment, the carbon spectrum appears along one axis and the proton spectrum along the other. Parameters may be chosen to emphasize large coupling constants to observe one-bond couplings, or to emphasize smaller couplings so that two- and three-bond couplings may be observed as well. A $^{13}C-^{1}H$-COSY spectrum showing one-bond couplings for ketoconazole is presented in Figure 5. In a related experiment, called relayed coherence transfer (RCT), parameters are used which give contours for each carbon atom corresponding to the directly attached protons as well as all the protons coupled to them (i.e. protons on nearby carbons).

2.3.2.4 Nuclear Overhauser Effect Spectroscopy In section 2.3.1.2 the 1-D NOE experiment was discussed. There is a corresponding 2-D version of this experiment which goes by the acronym NOESY (nuclear Overhauser effect spectroscopy). Although the $^{1}H-^{1}H$ version of this experiment is more popular with the pharmaceutical analyst, the $^{13}C-^{1}H$ version is also available. In the 2-D plot, contours are found for each pair of nuclei which would have produced a medium to strong NOE in the 1-D counterpart. In the 2-D experiment, some weak interactions that are detectable in the 1-D method are sometimes missed. However, in a single 2-D experiment one can get most of the results that would be obtained in many 1-D NOE experiments.

Figure 5 $^{13}C-^{1}H$-COSY spectrum of ketoconazole. Contours can be used to determine which carbon resonance (plotted along the side) is associated with each proton resonance (plotted along the top). This experiment was set up to determine which protons are directly attached to which carbon. By varying the acquisition conditions, it is possible to obtain a plot showing which carbons are 2 or 3 bonds away from each proton (data not shown).

During recent years, advances in NMR technology have led to techniques which provide increased sensitivity over these 2-D methods just discussed. These advances include the introduction of ''inverse'' or ''reverse'' detection probes, gradient probes, and decouplers which are capable of producing shaped pulses. These exciting advances mean that the pharmaceutical analyst can determine the structures of unknown samples with ever decreasing amounts of material.

2.3.2.5 Protein Techniques The proton spectra of individual amino acids are relatively easy to obtain and interpret. However, in proteins the large number of signals creates extensive overlap, making it impossible to interpret the normal 1-D spectrum. For larger proteins, even the 2-D experiments discussed previously are often not sufficient to allow chemical shift and structural assignments. Use of higher order (three-dimensional (3-D) and four-dimensional (4-D)) experiments has allowed the spreading of signals into more dimensions, making them more tractable. To perform many of these multidimensional experiments, it is necessary to have protein that is enriched (i.e. isotopically labeled) with ^{13}C and ^{15}N (and sometimes ^{2}H).

There are several problems involved in performing higher dimensional experiments. Each increase in dimension greatly increases the experimental time required to obtain the data. The multidimensional experiments require much higher concentrations of protein to reduce the amount of signal averaging for each acquisition. The 3-D and 4-D experiments require more complex spectrometer hardware and probes than the 1-D and 2-D techniques. The resulting data in the higher dimensional experiments also have reduced digital resolutions in some dimensions.

One class of 3-D experiments involves combining two 2-D ^{1}H experiments. This serves to reduce the overlap of signals by spreading them into the third dimension. The advantage of this type of experiment is that it does not require any isotopic labeling. A second class of 3-D experiments combines a 2-D ^{1}H experiment with a 2-D $^{1}H-X$ nucleus experiment (where X is usually ^{13}C or ^{15}N). This type of experiment takes advantage of the

wider shift range of the *X* nucleus and also allows the chemical shifts for the *X* nuclei to be assigned. This class of experiment requires that the protein be labeled with the *X* nucleus. Usually, data from several of these experiments are required to make full assignments for larger proteins. A third class of experiments is used to trace connectivities along the protein peptide backbone or along the side-chains. These experiments, which correlate three different nuclei (^{1}H, ^{13}C and ^{15}N), require doubly labeled protein. The NMR probes must have at least three frequency channels and the spectrometer must have as many as five transmitters. These experiments allow determination of correlations between sequential residues. For example, some experiments allow the correlation of the amide proton on one residue with the α-carbon of the preceding residue. Additional new experiments and refinements of older experiments have appeared over the last several years, and no doubt will continue to do so.

2.3.3 Hyphenated Techniques

One of the drawbacks of NMR spectroscopy has traditionally been its inability to easily positively identify small amounts of compounds in the presence of large amounts of other material. If the compound had resonances that were not overlapped with those of the main material, one could get some evidence of its presence and of its level, but because most of its resonances could not be observed, the identification usually had to be confirmed by another method. With techniques such as MS, gas chromatography (GC) or HPLC is used to separate each component before analysis. Over the last several years considerable work has been done on coupling NMR with HPLC in an analogous manner (see Keifer[9] and references therein).

A number of problems had to be solved in order to make HPLC/NMR a feasible technique for pharmaceutical research. One of the main concerns was with the sensitivity of NMR spectrometers. Since only small amounts of sample are injected onto analytical columns, older NMR instruments could not be used to detect the components coming off the column. Also, the mobile phase used on the HPLC systems gave rise to large peaks in the NMR spectrum, making it very difficult to observe the resonances for the drug-related material of interest. These problems have largely been addressed and HPLC/NMR spectroscopy is now a more routine, commercially available technique that is being used in many pharmaceutical laboratories around the world. There have recently been reports of combining this technique with MS (HPLC/NMR/MS) to produce a technique which is extremely powerful for pharmaceutical analysis.

Over the last few years there have been many reports of using NMR spectrometers as the detectors for a variety of other separation techniques. These include capillary HPLC, capillary electrophoresis (CE), capillary zone electrophoresis (CZE), and capillary electrochromatography (CEC). Although not yet commercially available, these techniques may soon provide pharmaceutical researchers with very powerful structural elucidation methods in their studies of drug-related materials.

3 APPLICATIONS

3.1 Confirmation of Known Compounds

While the majority of drugs may be just as easily identified by other methods, such as infrared (IR) spectroscopy and MS, NMR is used in many pharmaceutical laboratories. Some drugs that possess hygroscopic or polymorphic properties are difficult to analyze by IR spectroscopy. Also, many drugs fragment in such a manner that their mass spectra are ambiguous and difficult to interpret, especially in cases where there may be a number of closely related isomers. NMR provides an attractive alternative approach for these types of drugs since it is not affected by these kinds of problems and provides a very powerful method for distinguishing between isomeric drugs.

3.2 Identification of Unknown Compounds

NMR spectroscopy provides the analyst with one of the most powerful techniques for the identification of unknown compounds. For laboratories with modern spectrometers, the full range of experiments described in section 2.3 is available. While IR spectroscopy and MS are useful for identification of known compounds, especially by means of their library search capabilities, NMR is usually a key spectroscopic technique for identifying true unknowns.

The exact series of NMR experiments used to solve unknown structures may vary somewhat, depending on the preferences of the particular spectroscopist. However, the general procedure will be the same. The analyst will carry out the following series of experiments until enough information has been obtained to identify the unknown, or until enough information is obtained so that the investigator will be able to determine which specialized experiment is required to complete the study.

First, the drug-related sample is prepared for study as described in section 2.2. Then the spectroscopist obtains a high-resolution ^{1}H-NMR spectrum using an appropriate deuterated NMR solvent. Careful inspection of this spectrum gives a great deal of structural information. Chemical shifts and integration reveal the relative number of protons in each area (aliphatic, olefinic, aromatic) and the coupling patterns may reveal information on the proximity of many protons. Next, ^{13}C-NMR and

DEPT spectra are obtained to determine the number of different carbons and the numbers of protons attached to each. Chemical shifts of the carbons give important information about each carbon's environment. Often, the combination of proton and carbon data is enough to solve the structure of the unknown. If it is not, 2-D spectra and NOE experiments are used to establish connectivity and proximity of the nuclei in the molecule. The information obtained is often sufficient to establish the skeleton of the molecule. Sometimes, especially when there are NMR "silent" nuclei (such as chlorine, bromine, oxygen, nitrogen, etc.) present, it may be necessary to obtain MS and/or IR data in order to complete the structure. While it is true that spectra can be obtained for most of the "silent" nuclei, it is usually much quicker and easier to use these other spectroscopic techniques to establish their presence.

In studies to determine the identity of unknown compounds, it is often helpful to compare the NMR chemical shifts with those of related known substances. For example, if one were trying to identify drug metabolites or impurities, one could compare the spectra with those of the drug itself. If the chemical shift assignments are not already known, one can use the above sequence of experiments to establish them. Then, by determining which resonances are present in both and which have changed or disappeared, one can determine which part of the drug has changed. This is of particular advantage in cases where one has a relatively large amount of the drug and the amount of unknown available is small, thus limiting the types of experiments which may be performed on the unknown.

3.3 Quantification

When quantification is required, sample preparation procedures are more demanding than those for routine samples (discussed in section 2.2). If absolute quantification is required, the amount of sample used must be accurately known and an accurately known amount of a suitable standard must be added to the sample before the analysis. If only relative quantities of substances present are required, there is no need for an internal standard. If an extraction procedure is necessary, one must be sure that the drug-related material is quantitatively removed.

An appropriate internal standard must be chosen to ensure accurate quantification. This standard must meet a number of strict criteria. It must be pure (or at least be of known purity) and be soluble and stable in the solvent used for analysis. It must not react with any compounds present (including the solvent). For convenience, it is usually easier to work with a solid standard, but if a liquid is chosen, it should be nonvolatile in order to avoid losses during the sample preparation and analysis. Lastly, the standard must have an appropriate NMR spectrum such that both the drug-related material and standard have well separated resonances whose integrals or peak heights may be used in the quantification. It is usually best to choose a standard which has either a suitable singlet or narrow multiplet to minimize the chances of overlap of signal resonances.

The choice of nuclei for NMR quantification is important. For relatively simple mixtures, ^{1}H-NMR, because of the shorter relaxation times and higher sensitivity when compared with ^{13}C-NMR, is often the method of choice. However, for more complex mixtures, ^{13}C-NMR may prove to be the better option. Although NMR is well suited for quantification of drugs, relatively few publications have appeared in this area. In part this is due to the fact that this method is considered to be so routine as to not warrant publishing these kinds of results. More recently, however, a number of publications have appeared (e.g. Lacroix et al.[10,11]) which show that NMR gives analytical results comparable to those obtained by other methods, such as HPLC (see sections 3.4 and 3.5). These papers point out the advantages of NMR over these alternative methods, indicating that NMR should be used more routinely for quantification purposes.

There are basically two approaches to obtaining the accurate quantification of drugs or impurities by NMR techniques. In the first, one must wait a relatively long time ($>5\,T_1$ for the longest relaxation time) to ensure equal responses for each of the nuclei being studied. The second method requires that spectra be acquired and processed under identical conditions and that a calibration curve, with appropriate amounts of the standard and analyte covering the range of interest, be obtained. The first method has the advantage of not requiring pure compounds (used to create the calibration curve in the second) because the relative response of the nuclei is known. Its main disadvantage is the amount of time required to acquire the spectra due to the long relaxation delay between pulses. Another disadvantage appears in the processing of the data. Because of differences in peak widths, areas from integrations must be used and care must be taken to avoid problems due to baseline distortions which may adversely affect the analyses. The second method has the advantage of shorter acquisition times for the spectra, but requires that appropriate standards be available and calibration curves be obtained. Another advantage of the second method is that because a calibration curve is being used, it is possible to use peak heights instead of areas (although areas may still be used). Using peak heights with calibration curves has allowed the simultaneous quantification of a relatively large number of impurities in the drug fenofibrate[10] at relatively low levels (<0.1%). This is considerably better than results reported for other drugs using integration, where the lower limits are reported to be about 1%.

3.4 Impurity Profiling

When a ^{1}H-NMR spectrum is taken for a drug, signals are obtained for the protons of the impurities as well as for the pharmaceutical itself. Careful examination of these ''extra'' peaks will often allow the identification of one or more impurities. Integration, or comparison of relative peak heights, will usually give a very good estimate of the percentage of each impurity present. As long as there are unique resonance peaks for each impurity, large numbers of impurities may be quantified from a single spectrum. This was amply illustrated by Lacroix et al.[10] for the drug fenofibrate. In this study, 12 known impurities, as well as a number of unknowns, were quantified at levels of <0.1% in drug raw materials from several manufacturers.

In cases where the impurity(ies) cannot be identified in the presence of the drug, it is often possible to separate it (them) from the drug using the extraction methods discussed in section 2.2. Once the drug resonances no longer mask the impurity peaks, it is much easier to perform the required NMR techniques to identify the material. Alternatively, if an HPLC method exists for separating the impurity, the eluted peak may be collected and analyzed by NMR. If the HPLC and NMR are interfaced, the impurity may be studied without having to go through the collection step.

3.5 Optical Purity

For a number of drugs only certain optical isomers are supposed to be present in the commercial product. Using the methods described in section 2.3.1.4, NMR methods for determining the optical purity for many of these drugs have been reported. Most of the earlier studies were done on lower-field-strength instruments, using CLSRs. The limit of quantification for these studies was typically 1–5%. The later studies, using higher-field-strength instruments and CSAs or CDAs provide much greater sensitivity, with detection limits in some cases of much lower than 0.1%. For example, Lacroix et al.[11] used (*R*)-(−)-2,2,2-trifluoro-1-(9-anthryl)ethanol with drug raw material for timolol maleate, enabling them to easily detect the optical impurity at levels of 0.1% at a relatively low field strength (400 MHz). These kinds of results make NMR a very attractive method for determining if pharmaceutical products meet the requirements set by pharmacopoeias of many countries.

3.6 Analysis of Body Fluids

In many cases analysts studying drug metabolism will analyze samples of body fluids in attempts to measure levels of the drugs and/or their metabolites. The concentration of drugs in the blood varies over a wide range – from tens of milligrams per milliliter for ethanol to nanograms per milliliter for most drugs and their metabolites. However, in some extreme cases of overdoses, drug levels of 100 mg mL^{-1} are observed. The lower ranges of these drug and metabolite levels are beyond the sensitivity of NMR, but the higher end values are not. Detection limits for ^{1}H-NMR are below the microgram per milliliter range on newer high-field spectrometers using the hyphenated techniques discussed in section 2.3.3. Without these methods, it has proved difficult to obtain these lower limits due to the background signals from endogenous compounds in the blood and urine samples. The fluorine signals of fluorinated steroids are detectable at submicrogram-per-milliliter levels because there is no background. For nonfluorinated drugs, analysts who do not have access to the hyphenated techniques have the option of performing sample work-up procedures such as solid-phase extraction (SPE) or preparative HPLC clean-up before analysis. This also allows the analyst the opportunity to concentrate the drug or metabolite from several milliliters down to the volume (<0.5 mL) required for NMR analysis, thus bringing many more samples into the range of levels detectable by NMR.

4 COMPARISON WITH OTHER TECHNIQUES

4.1 Advantages

NMR will detect all organic compounds present in the sample. Other techniques, such as HPLC or MS, will often not detect impurities. For example, these techniques will not observe any compounds that either elute in the solvent front or do not come off the column at all under the conditions used. Careful examination of the impurity peaks in the NMR spectrum will often give significant clues as to their identity and allow quantitative estimates as to the amounts present. HPLC provides little information about the identity of unknown impurities and is not reliable for quantifying them since it does not give equimolar responses for different materials. In fact, compounds with low or no ultraviolet (UV) absorbance may not be detected, even when present at significant levels.

NMR is a nondestructive technique. As long as the sample material is stable in the solvent chosen for the study, the entire sample may be recovered and then used for other studies. Thus, since sample is used up in other techniques such as HPLC and MS, the NMR studies should be performed first whenever there is a limited amount of sample.

NMR spectroscopy provides the most powerful structure elucidation technique available to the pharmaceutical analyst for unknown materials. One area where

NMR outshines other spectroscopic techniques is in the determination of isomers. Its true value comes from its ability to establish the proximity of nuclei in a molecule using coupling constants (through one, two or three bonds) or with NOE measurements (for nuclei within approximately 5 Å). The NMR chemical shifts and coupling constants easily allow the discrimination of geometric or positional isomers, even when there are no authentic materials for comparison purposes. It would be much more difficult, if not impossible, to get this same information using other spectroscopic techniques such as IR spectroscopy or MS (without reference standards).

The most common method for an analyst to determine the optical purity of drugs has been by either specific optical rotation or HPLC, using a chiral column or a chiral derivatization procedure. However, NMR has a number of advantages over optical rotation and HPLC in studies aimed at determining the enantiomeric composition of any organic compounds, including pharmaceuticals. This is especially true if methods are required that are capable of analyzing for optical antipodes at levels of less than a few percent. This may be important if one wishes to confirm that a pharmaceutical meets the requirements of a country's pharmacopoeia. Using modem spectrometers and the techniques described previously, it is usually possible to develop methods that can quantify the drug's enantiomer at or below levels of 0.1%. Some of the advantages of NMR are given here.

1. NMR results are accurate and precise, even at low percentages. Optical rotation cannot be used to determine low levels of impurity, especially in drugs with a low specific optical rotation.
2. The time required for analysis is usually less for NMR than for HPLC. This is especially true if there is no existing method, since it is usually quicker to develop an NMR method than an HPLC method. If a method already exists, it is still much faster to get the results by NMR. For NMR, the procedure would normally involve simply dissolving the drug in an appropriate solvent, adding the calculated amount of CSA, acquiring the proton spectrum and measuring the proper peaks in the spectrum. This may normally be done within half an hour. For HPLC, one must set up the liquid chromatography system (put in the proper column, prepare the mobile phase, etc.), check the performance of the column by running a standard and then run the sample. All this requires much more than half an hour.
3. NMR methods are more ''robust'' than HPLC methods. Once a method has been developed for NMR, it should work on any spectrometer of equal field strength (or higher field strength for CSAs and CDAs). Because of the variability of columns, HPLC methods have to be checked and sometimes modified when changing columns.
4. NMR provides ''bonus'' information. Since NMR detects all signals for the nucleus under study, it will detect not only the drug (and its enantiomer), but also any impurities present.

4.2 Disadvantages

One of the main criticisms of NMR as an analytical technique is its relative insensitivity when compared with other methods such as MS or HPLC. While these other instruments may require only nanograms or less of the sample, NMR usually needs micrograms or more. While this limitation is of little concern for drug raw materials or dosage forms, it does limit its use in analyses of body fluids for drugs and their metabolites.

Another common complaint about NMR is the cost of the instrumentation. While it is true that highest-field-strength spectrometers are very expensive (millions of dollars each), the models that have been around for several years (currently field strengths of 200–600 MHz) tend to be comparable in cost to mass spectrometers. In general, NMR spectrometers have proven to be very reliable instruments, with relatively low repair and maintenance costs. Thus, if one considers the cost per year, NMR spectrometers may not be as expensive as is generally thought.

Another concern often brought up when discussing the use of NMR is the need for highly specialized expertise in the area. While it is true that considerable expertise is required in order to take advantage of the full capabilities of modern spectrometers, very little knowledge is needed to use NMR results for more routine purposes. Thus, for positive identification of known compounds, simple comparisons of spectra with those of authentic materials is all that is required. This is very similar to the use of IR spectroscopy ''fingerprinting'' to identify compounds. It is also possible to automate the identification by use of library searches of NMR databases, comparable to those for IR spectroscopy or MS.

5 CONCLUSIONS

NMR has played a key role in pharmaceutical analysis in the past and promises to play an even more crucial role in the future. The ever increasing sensitivity and capabilities of the most modern spectrometers provide pharmaceutical analysts and researchers with more powerful tools to tackle their analytical problems. There is no doubt of the vital role to be played by NMR in studies

of the newer biotech pharmaceuticals in the areas of structure and drug interactions. In studies of traditional synthetic drugs, NMR, especially in conjunction with other analytical techniques such as MS and HPLC, will continue to have a critical function.

Planar chromatography is a liquid chromatography in which the stationary phase is arranged in the form of a planar or flat bed and the mobile phase moves by capillary action. Thin-layer chromatography (TLC) is the most widely used planar chromatography. Modern TLC is an instrumental version of conventional TLC known as high-performance thin-layer chromatography (HPTLC). Rotation planar chromatography (RPL), high-speed thin-layer chromatography (HSTLC), and over-pressured liquid chromatography (OPLC) are some other forms of planar chromatographic methods.

The application of HPTLC techniques for pharmaceutical analysis, such as the determination of active pharmaceutical ingredients (API) and the content uniformity test (CUT) of dosages, purity and stability tests of drugs and drug products, process monitoring of formulations, and herbal drug analysis, is described in this article. The method development of the high-performance liquid chromatography (HPLC) technique, various pharmaceutical regulations and methods, validation and quality assurance (QA) of HPTLC experimental data and documentation are also described. The comparison of HPTLC with other chromatographic techniques is also discussed.

1 INTRODUCTION

Planar chromatography is a liquid chromatographic technique in which the stationary phase is arranged in the form of a planar or flat bed and the mobile phase moves by capillary action. The most widely used planar chromatography is TLC. Modern TLC is a fully instrumented version of conventional TLC, also known as HPTLC. In HPTLC perfectly uniform surfaces, 150–200 μm in thickness, are prepared from particles with a narrow size distribution, typically with diameters between 5 μm and 15 μm.

HPTLC is an off-line technique where every stage of the analysis protocol can be visualized. It is capable of providing faster separations, better separation efficiency, reduced zone diffusion, higher sensitivity, and more accurate quantification than other techniques for a wide variety of applications. The optimized instrumentation coupled with high levels of automation offers precise control over sample application, chromatographic development, derivatization, detection, and determination. The special feature of HPTLC is its ability to simultaneously spot, develop, and automatically scan a number of separations on a single plate. Typically, 18–36 samples can be run on a single plate with development times of 3–20 min over migration distances of about 2–7 cm using 2–5 μL of loading sample. HPTLC has a higher detection limit than HPLC, but this can be overcome by sample postchromatographic derivatization or by bioautography. The greatly increased development time on HPTLC chromatoplates has made it necessary to employ forced flow of the mobile phase instead of capillary flow. This feature has been exploited in RPL. In HSTLC electroosmosis is employed to force the eluent. OPLC is the true planar version of HPLC, where pressurized flow is developed using a pump system for admission of the mobile phase.

Pharmaceutical analysis is traditionally defined as the branch of analytical chemistry dealing with drugs, both

as bulk drug substances and pharmaceutical products (formulations). This article is concerned mainly with planar chromatography together with capillary flow, namely HPTLC for pharmaceutical analysis.

2 HISTORY

The history of TLC has been reviewed by several authors.[1–7] Ismailov and Shraiber separated certain medicinal compounds on an alumina spread on a glass plate, in 1938. Meinhard and Holl in 1949 used a binder to adhere alumina to microscope slides to separate certain inorganic ions. In the early 1950s, Kirchner and colleagues used sorbents held on glass plates with the aid of a binder, and the plates were developed with the conventional ascending procedure used in paper chromatography. Stahl introduced the term "TLC" in the late 1950s. Quantitative TLC was introduced in 1954 by Kirchner et al.[8] Densitometry in TLC was initially reported in the mid-1960s by Dallas et al.,[9] Genest,[10] and Thomas et al.[11] HPTLC plates having fine particle layers were produced commercially in the mid-1970s, and in the late 1970s forced-flow planar chromatography was introduced.

TLC will continue to grow as a highly selective, sensitive, quantitative, rapid, and automated technique for the analysis of all types of samples and analytes, and for preparative separations.

3 SAMPLE PREPARATION

Sample preparation for TLC is not as demanding as for other chromatographic techniques as the plates are disposable products. However, several steps for sample pretreatment may be necessary, which include mechanical crushing, extraction steps, filtration and sometimes enrichment of interesting desired components, or removal of undesirable impurities. Proper sample preparation is an important prerequisite for the success of TLC separation. The sample preparation procedure is to dissolve the drug with complete recovery of intact compounds of interest and minimum of matrix with a suitable concentration of analytes for direct application on the TLC or HPTLC plate. Besides maximizing the yield of analytes in the selected solvent, the stability of analytes during extraction and analysis must be ensured. Therefore, the choice of a suitable solvent is very important. For normal-phase chromatography using silica gel-precoated plates, the solvent for dissolving the sample should be nonpolar and volatile as far as possible. This is because polar solvents are likely to induce circular chromatography when the sample is employed incrementally, leading to spreading of the spot and thus loss of separation efficiency. For reversed-phase chromatography polar solvents are usually used for dissolving the sample; however, such polar solvents must wet the layer so that the sample penetrates the layer uniformly. It is preferable to use the minimum possible amount of solvent, the quantity employed being limited to ensure complete extraction of analytes but the minimum of extraneous components. Sample and reference substances should be dissolved in the same solvent to ensure comparable distribution at the starting zone. Most sample preparation procedures require concentration or evaporation of the sample extracts. It is important that evaporations are carried out without loss or degradation of the analyte. Common methods for concentration are rotary evaporation and nitrogen blow down. Common practice is to evaporate solutions just to dryness and then to dissolve the residue in an exact volume of the same or different solvent from which a known aliquot or the total sample is applied to chromatoplates.

4 PHARMACEUTICAL APPLICATIONS

There is a comprehensive literature dealing with TLC systems for pharmaceutical analysis.[12–26] Manufacturers of HPTLC instrumentation provide instrument validation and support for all users performing analysis in the fields of herbal, bulk drugs, and pharmaceutical formulations. Pharmaceutical applications of HPTLC analysis are summarized in Table 1. The only limitation of HPTLC

Table 1 Uses of HPTLC in the pharmaceutical industry

Industry sector	HPTLC analytical task
Manufacturing	Process monitoring, fermentation broth analysis, cleaning, and residue analysis
QC	Raw material assay, multicomponent formulations, uniformity of content, individual container analysis, impurity profiles
Formulation (research and development)	Formulation analysis, stability studies, sustained release, bioequivalance studies
Synthesis (research and development)	Process optimization, preparative chromatography
Crude drug	Fingerprinting, active ingredient quantitation, label claim check, preparative analysis, adulteration check

QC, quality control.

DEA, diethylamine; UV, ultraviolet.

so far as pharmaceutical analysis is concerned is that it cannot be employed for dissolution testing studies.

4.1 Pharmaceutical Products

Drugs are defined as substances or products that are intended for modification or exploration of physiological states for the recipient. The drugs are prescribed in a variety of forms such as tablets, capsules, injections, ointments, intravenous fluids, syrups, etc. termed as pharmaceutical products, formulations, or dosage forms. As HPTLC requires minimal sample cleanup, interference from the excipients in tablets, the high quantity of fatty matter in creams, and the sugar base of lozenge formulations pose no problems in HPTLC analysis. Therefore, the active drug components either in single or mixed dosage forms are estimated economically and speedily. Table 2, summarizes HPTLC applications for the determination of the API from formulations.

As specified in *United States Pharmacopeia* XXIII, dosage forms containing 50 mg or less of active ingredient per unit must comply with a CUT. The criteria specified is that out of 10 units individually tested the contents of each unit must be within 85–115% of the labeled claim with a relative standard deviation (RSD) not greater than 6.0%. However, if one unit is outside the 85–115% range of the labeled claim and no unit is outside 75–125%, or of RSD not greater than 6.0% or both, 20 additional units must be tested. Not more than one unit out of 30 so tested is to be outside the range 85–115% and no unit is to be outside 75–125% with RSD not above 7.8%. These tests are laborious and time-consuming. However, HPTLC has been found to be the most suitable and economically viable method for testing the dosage form for compliance in respect of content uniformity. Using the built-in CUT feature in CATS software, three complete CUTs can be performed in 2 h. (CATS software is a Windows-based software used in quantitative TLC and is supplied by CAMAG, Switzerland.)

4.2 Purity Profiles

The purity of a drug and the determination of the nature and quantity of any impurities present are key questions for the modern pharmaceutical analyst. The nature and the quantity of impurities in a drug product depend upon the route of synthesis used to produce the drug substance (bulk drugs), purification procedures, manufacturing of pharmaceutical products or formulation, and the conditions under which they have been stored. Purity tests of bulk drugs are generally focused on related substances such as homologs, analogs, by-products from the synthesis or degradation, and the enantiomeric purity. HPTLC has revolutionized the ability to determine substance purity and is currently the most important check, giving essentially the fingerprint of a synthesis.

Low-level substances with relatively high retention times are poorly resolved and detected owing to peak broadening in HPLC. However, in reversed-phase high-performance thin-layer chromatography (RPHPTLC) substances with low R_f (retention factor) values form strong and sharp zones, and hence have better detection sensitivity. Those substances with low retention times may appear as unresolved in HPLC, but in RPHPTLC they will usually appear between R_f values of 0.5 and 0.9 and are easily detected. In RPHPTLC, the impurities can be detected either at the starting line or near the solvent front provided the plates have been properly alleviated by prewashing prior to development. Large quantities of slowly eluting substances would completely spoil the HPLC column after collection and may show memory effects, whereas slowly migrating substances in RPHPTLC will be retained near the origin.

When studying the purity profile of drugs using HPTLC, the following precautions should be considered:

- After the TLC plates have been developed, they should not be dried at an elevated temperature. This avoids any decomposition, oxidation, and hydrolysis during drying.

- The solvents to be used for sample preparation or as components of mobile phase should be checked by running a blank TLC plate in the solvent. The plate should not show any spot visible under UV light or with the reagent likely to be used for the detection of impurities. This is absolutely essential because any impurity present in the solvent can give erroneous results, in that the additional spots can be mistaken to have been contributed by the substance under examination.

The application of HPTLC to the purity profile study of some drugs is illustrated by the densitograms in Figures 1–3.

Commercially available chiral HPTLC plates have made it easy to purify and quantify enantiomeric drugs. Optical purity control of L-dopa and D-pencillamine (Figures 4 and 5) are two excellent examples showing the application of HPTLC for enantiomeric drug separations.

4.3 Stability Studies

The purpose of stability testing is to provide evidence on how the quality of a drug substance or pharmaceutical product varies with time under the influence of a variety of environmental factors such as temperature, humidity, and light. Stability testing permits the establishment of recommended storage conditions, retest periods, and shelf lives.

Figure 1 Densitogram of the purity profile of theophylline scanned at 274 nm using Camag scanner II with CATs software; silica gel 60 F_{254} HPTLC plates; toluene–2-propanol–acetic acid (16 : 2 : 1 v/v) as mobile phase; unsaturated twin-trough chamber. (Reprinted by permission of publisher Research Institute for Medicinal Plants, Hungary from *J. Planar Chromatogr.*, **8**, 271 (1995).)

Figure 2 Densitogram of the purity profile of estradiol benzoate scanned at 229 nm with TLC Camag scanner II with CATs software, silica gel 60 F_{254} HPTLC plates; hexane–acetone–2-propanol (90 : 5 : 5 v/v) as mobile phase; unsaturated twin-trough chamber; I estradiol; II estradiol benzoate; III estradiol-3-benzoate-17-acetate; IV estradiol dibenzoate. (a) A typical batch (100 µg of estradiol). (b) batch spiked with impurities. X – is the impurity of unknown identity. Figure 3 Densitogram of the purity profile of danazol scanned at 252 nm with TLC Camag scanner II with CATs software, silica gel 60 F_{254} HPTLC plates; chloroform–ethyl acetate (88 : 12 v/v) containing 0.02% ethylamine as mobile phase; unsaturated twin-trough chamber; I, II, III are impurities; IV is danazol. (a) A typical batch of danazol (100 μg). (b) batch spiked with impurities. (Reprinted by permission of publisher Research Institute for Medicinal Plants, Hungary from *J. Planar Chromatogr.*, **6**, 199 (1993).)

Information on the stability of a drug substance or dosage from under defined storage conditions is an integral part of a systematic approach to stability evaluation. Stress testing helps to determine the intrinsic stability characteristics of a molecule by establishing degradation pathways to identify the probable degradation products and to evaluate the stability by indicating the power of the analytical procedure used.

HPTLC has been employed as a stability-indicating method for stability studies of several drugs and formulations. Three such examples are illustrated in Figures 6–8.

4.4 Process Monitoring

Profitability is directly linked to production efficiency, which in turn can be established by numerous research and development experiments. Each such experiment must be monitored closely. Based on the results of the impurity profile of the drug, the process is modified. Thus an assurance of product quality and consistency is very much in the hands of analysts. In process analysis the assay is performed either by the production department or the QC laboratory. Production departments are therefore equipped to conduct those types of in-process controls necessary to keep the process running, whereas controls that might require special equipment are conducted by the QC laboratory. The methods should be very easy to perform, fast, accurate and reproducible. They should help in the processing of drug substances during intermediate stages. Chances of contamination from previous processes is to be monitored and indicated.

HPLC and HPTLC are the two most widely used techniques in the pharmaceutical industry for process control. Process optimization needs hundreds of quick analyses, which are well executed by an HPTLC system at a low cost. Moreover one HPTLC system can support several laboratories simultaneously.

The drug norfloxacin is produced by condensing 3-chloro-4-fluoro aniline (CFA) and diethyl ethoxy methylene malonate first to yield the acrylate which, on further cyclization, yields the *N*-ester. On ethylation this ester gives the ethyl-*N*-ester which, on hydrolysis, gives acid and norfloxacin. This production of norfloxacin can be monitored by HPTLC technique, as all the compounds have absorption in the UV region at 288 nm. The densitogram of a typical production batch of norfloxacin is shown in Figure 9. The production process optimization and monitoring of oxfendazole can also be performed using HPTLC (Figure 10).

4.5 Herbal Drugs

Plant substances have been used in medicines since ancient times. The composition of the drug varies widely depending on the species, geographical location, origin, climate, growth period, part of the plant, storage, and preparation procedure. Herbal formulations used in the preparation of therapeutic medicines derive their potency from constructive and symbiotic effects due to the presence of two or more crude drugs. This makes the analysis of herbal formulations more complex.

Figure 4 Chromatoplate showing the optical purity of L-dopa. Layer, Chiralplate™; eluent, methanol–water–acetonitrile (50:50:30 v/v/v); developing time, 45–60 min; detection, 0.1% ninhydrin reagent. 1 = L-dopa; 2 = D,L-dopa; 3 = D-dopa; 4 = 3% L-dopa in D-dopa; 5 = 3% D-dopa in L-dopa. (Reprinted by permission of K. Gunther, from *Z. Anal. Chem.*, **322**, 513–514 (1985).)

Figure 5 Chromatoplate of optical purity of D-pencillamine. Layer, Chiralplate™; eluent, methanol–water–acetonitrile (50:50:200 v/v/v); developing time, 30 min; detection, 0.1% ninhydrin spray reagent. 1 = L-5,5-dimethyl-4-thiozolidine carboxylic acid (L-3); 2 = D,L-5,5-dimethyl-4-thiozolidine carboxylic acid (D,L-3); 3 = D-5,5-dimethyl-4-thiozolidine carboxylic acid (D-3); 4 = 3% L-3 in D-3; 5 = 3% D-3 in L-3. (Reprinted by permission of K. Gunther, from *Arch. Pharm. (Weinheim)*, **319**, 461–465 (1986).)

HPTLC has been found to be the most accurate and facile technique for the analysis of herbs and their extracts over other techniques for the following reasons:

- Very little sample clean-up is needed as the layer is disposable.
- Preparative work can be very easily done.
- Fingerprinting of a large number of components of the sample matrix is possible.
- Active ingredients can be quantified.
- Short run times.
- Large numbers of analyses are possible, for reliable statistics.
- Many components in herbal medicines are fluorescent.

Figure 6 Densitogram of the stability profile of oxytetracycline eye drops scanned at 254 nm. Layer, silica gel TLC plates impregnated with aqueous solution of disodium ethylenediaminetetraacetic acid and activated at 130 °C; eluent, chloroform–methanol–water (65 : 25 : 5 v/v/v); saturated TLC tank. (a) On the day of the preparation, (b) On the 10th day of storage. Peaks: 1 = α-APC-OTC (α-apoxytetracycline); 2 = EOTC (4-ethoxytetracycline); 3 = OTC (oxytetracycline hydrochloride); 5 = β-APC-OTC (β-apoxytetracycline); 4,6,7 and 8 = unidentified; 9 = solvent front caused by demixing. A large number of papers on the application of planar chromatography to the characterization of herbal medicines have been published in Chinese journals. Table 3 shows HPTLC applications for herbal formulations.

5 PHARMACEUTICAL REGULATIONS AND METHODS

There are several regulations that have to be followed in the development of pharmaceuticals as well as in their production. Regulatory approval is required prior to the investigational new drug (IND) application, before initial human testing, and also the new drug application (NDA) which summarizes the data obtained from all the studies needed for marketing approval of the drug as a medicine.

An important part of the development process is safety evaluation, primarily the toxicology tests, which run from 6 to 24 months in different species. By this time bioanalytical studies have been performed, as well as control of the formulations used in the tests. After approval for marketing the authorities exercise control of products on the market and require past production stability data. Public interest in the quality of drugs is also reflected in the compilation of substance monographs in compendia, known as pharmacopoeias, which contain

Figure 9 Densitogram of process control for the synthesis of norfloxacin. Layers, 60 F_{254} silica gel on aluminum sheet HPTLC plates (Merk); mobile phase, toluene–ethyl acetate–glacial acetic acid (10 : 3 : 4 v/v/v); twin-trough chamber; Camag TLC scanner with CATs software; detector wavelength 254 nm. Precoated HPTLC (Merk) plates; twin-trough chamber (Cmag); mobile phase, *n*-hexane–ethyl acetate–acetic acid (50 : 45 : 5 v/v/v); detector wavelength 254 nm. (Reproduced by permission of Dr. P.D. Sethi from *High-performance Thin-layer Chromatography. Quantitative Analysis of Pharmaceutical Formulations*, CBS Publishers and Distributors, New Delhi, 1996.)

general analytical methods and also requirements on the formulation of the substances.

Good Manufacturing Practice (GMP) regulations have been a cornerstone of pharmaceutical production and control since the 1970s. These regulations state clearly what has to be done to safeguard quality from the beginning of the production process to the end, namely documentation, staff qualifications, standard of facilities, technical standards, handling of material, labeling, etc. Control guidelines are mentioned but not in the same detail as in current good laboratory practice (GLP). These rules state that all documentation of analytical methods should fulfil certain performance criteria, that

Table 3 HPTLC of some herbal formulations

Mobile phase	λ (nm)	Compounds	Remarks	Ref.
Hexane–ethyl acetate (2 : 1)	268	Phyllanthin and hypophyllanthin	In phyllanthus amurus and polyherbal preparations	53
Hexane–ethyl acetate (1 : 1)	260 and 409	Phyllanthus	Fingerprinting evaluation for shelf preparation	54
Hexane–ethyl acetate (2 : 1)	254	Phyllanthus	For rational search for antihepatotoxic agent	55

Ethyl acetate–methanol–13.5% ammonia	264	18-β-Glycyrrhetinic acid	In polyherbal preparations of liquorice syrup, cream, tablets	60
Chloroform–ether–methanol (5 : 2 : 1)	560	Madecassic acid	Tablets and capsules containing *Centella asiatica*	61

Stationary phase is silica gel.

instruments should have maintenance records, and that their performance and those of the method should be documented. Every analyst should in principle document an analytical method and its aims.

Since the late 1970s various leading drug regulatory bodies such as United States Food and Drug Administration (USFDA), World Health Organization (WHO) and Commission of Pharmaceutical Manufacturing Product (CPMP) of the European communities, in consultation and collaboration with various research organizations and industries, have been monitoring the efficacy of various drugs. The Centre for Drug Evaluation and Research (CDER) in the USA is one of the leading agencies which issues timely guidance as regard to various current GMP norms, formulation designs, and biostudies.

Owing to the stringent regulatory and ethical requirements, it becomes equally important to monitor the quality of drug substances with respect to their identity, potency, purity (including chiral purity), and dosage at the time of release and at various stages of shelf life. These are achieved through analytical techniques. The analytical results form the basis of the evaluation of drugs and pharmaceutical products, demonstrating their quality, efficacy and safety during drug development and product registration, and verifying their quality in QC process. Rapid and cost-effective provision of suitable results are, therefore, a fundamental challenge in pharmaceutical analytical chemistry.

Analytical methodology is in a period of transition due to technological advances and modified policies of the governmental regulatory agencies. In many countries the regulations and the practices of drug manufacturing have changed because of the recently developed ability of analysts equipped with modern instrumentation to determine low concentrations of impurities. Although HPLC is the method of choice, HPTLC is becoming increasingly popular in the field of pharmaceutical analysis.

6 VALIDATION AND QUALITY ASSURANCE

6.1 Analytical Method Validation

Analytical method validation is a summary of several validation steps involving exact proof and evaluation of the suitability, correctness, and precision of each chromatographic and nonchromatographic step and of the instrumental components. Regulatory recommendations have been developed to promote correct analytical method validation through ICH (International Conference for Harmonization) guidelines, and several articles have been published covering TLC.[15,16,19,24,62,63]

Table 4 summarizes the validation parameters specific to planar chromatography for pharmaceutical analysis. Errors originating from sample preparation, application, calibration, etc. are evaluated and the selectivity of separation and peak purity are checked. If pure standards of each analyte are available, the information may be obtained by carrying out chromatographic analysis of each standard separately under the predetermined experimental conditions. Assessment of peak purity is best performed by subjecting samples to appropriate stress conditions in order to produce decomposition products; peak overlapping may then be more easily recognized. The chromatograms of treated and untreated samples either unspiked and spiked with known concentrations of impurity standards are recorded at two or three preselected wavelengths. Any change in peak shape resolution, or peak symmetry, determined by comparing the chromatographs obtained from treated and untreated samples,

Table 4 HPTLC validation parameters for pharmaceutical analysis[a]

Validation characteristics	Types of analytical procedure		Limit	Assay content/potency
	Identification	Quantitative testing for impurities		
Accuracy	−	+	−	+
Precision:				
– Repeatability	−	+	−	+
– Intermediate precision	−	+[b]	−	+[b]
Specificity[c]	+	+	+	+
Detection limit	−	−[d]	+	−
Quantitation limit	−	+	−	−
Linearity	−	+	−	+
Range	−	+	−	+

[a] + signifies that this characteristic is normally evaluated, − signifies that it is not.
[b] In cases where repeatability has been measured, intermediate precision is not needed.
[c] Lack of specificity in one analytical procedure can be compensated by other supporting analytical procedure(s).
[d] May sometimes be needed.

can indicate nonhomogeneity of a chromatographic peak. Peak homogeneity can also be investigated by two-dimensional chromatography using a different mobile phase in the second direction to the first direction of mobile-phase flow. After trying various mobile-phase compositions during the second run and if single peak chromatograms are obtained the peak can be considered as a pure one.

The ruggedness testing of HPTLC is performed by three different analysts trained in HPTLC, analyzing the same sample under the same experimental conditions to determine problems with reproducibility of the method. Various experiments to be performed for testing HPTLC ruggedness are tabulated in Table 5. The results of evaluation are reported as a percentage of the RSD. A TLC method is judged to be rugged when the system still yields acceptable RSD results in all variations and it passes the system suitability test (Tables 6 and 7). Any parameters favorably influencing the result must be reported and the degree of control must be specified.

Table 7 System suitability data specific to planar chromatography

Test	Data to be checked[a]		
	A	B	C
Orientary R_f value	+	+	+
Minimum value of peak symmetry	+	+	+
Maximum value of peak symmetry	+	+	−
Desired peak weight	+	+	+
Detection limit	+	−	−
Limit for quantification	+	−	−
Precision (for IQ)	+	+	+
Precision (for QSP)	+	(+)	(+)

[a] A = full test – the method is used after a long period of time or it is an attempt to use the method for a different analytical purpose; B = basic test – the method is in continuous use on the same analysis but something, such as the chromatoplate, has been replaced; C = abbreviated check – the system is in continuous use under the same experimental conditions; − = check is not required; + = to be checked; (+) = to be checked if necessary.

6.2 Quality Assurance of Experimental Data and Documentation

QA of the experimental data is an important topic in method validation. If the results of the method validation fails, the QA function rejects the analytical results giving instructions to the analyst to repeat the method developed. The second function of QA includes the documentation activities of the method validation, such as

Table 5 Ruggedness testing of different HPTLC operations

Operation	Experiments performed for ruggedness checking
Sample preparation	Vary shaking time, pH, temperature, and the composition of the extracting solvents phase ratio and the number of extractions
Sample application	Vary effects of spot shape, size, and stability
Separation	Vary chamber system, mobile phase composition, temperature, and development distance for at least three different plates of the same or different samples
Spot visualization (postchromatographic derivatization)	Vary spraying or dipping conditions, temperature, and reaction time
Quantitative evaluation	Vary conditions for drying plates and detection wavelength

Table 6 System quantification and analytical tasks specific to planar chromatography

Data to be checked	Identification			Purity testing			Assay			Stability test		
	IQ	SSQ	QSP	IQ	SSQ	QSP	IQ	SSQ	QSP	IQ	SSQ	QSP
R_f or R_m values from five replicate applications of the standard solution	−	+	−	−	+	−	−	+	−	−	+	−
Precision calculated from five replicate applications of the standard solution	−	−	−	+	−	−	+	−	−	+	−	−
Precision calculated from three parallel runs of spiked placebo or blank solutions with different concentrations of analytes. Each concentration of sample is applied in triplicate	−	−	−	−	−	(+)	−	−	(+)	−	−	(+)
Peak symmetry	−	+	−	−	+	−	−	+	−	−	+	−
Peak height for one or more peaks	−	−	−	+	−	−	+	−	−	+	−	−

$R_m = \log[(1 - R_f)/R_f]$.
IQ, instrument qualification; SSQ, separation system qualification; QSP, qualification of sample preparation; − = check not required; + = to be checked; (+) = to be checked if necessary.

- compilation of the validation package;
- creation of standard operating procedures (SOP) for satisfactorily validated analytical methods according to GLP requirements;
- statistical assessment of the methodology.

To demonstrate adequate performance of the TLC system, all results must be documented and criteria formulated that should be controlled prior to the use of the TLC system (system suitability test). The necessary items for documentation are as follows:

1. Listings of:
   (a) all samples used for the experiments including sources, lot numbers, analytical results, and storage conditions;
   (b) all required instrumentation used, together with their manufacturing companies and model numbers;
   (c) all necessary reagents used for sample preparation, their required dilutions or mixtures, and storage conditions indicating shelf life;
   (d) all materials and reagents used for mobile-phase preparation including their required dilutions and mixings in detail;
   (e) type, particle size, dimensions, and thickness of chromatoplates used;
   (f) type and size of chamber used for the experiments, experimental conditions such as sample applications, temperature, saturation, developing distance, etc.;
   (g) visualization techniques including detailed description of preparation of spraying reagents, spraying conditions;
   (h) detection parameters.
2. Detailed description of the entire analytical process including sample preparation, standard preparation and step-by-step procedure (including any presaturation, preequilibration, weights, volumes, extraction times, solvent range adjustments, centrifugation times), method for evaluation and calculation.
3. Summary of developmental data for formulated products.
4. Degradation scheme for the active ingredients and for formulations.
5. All validation data, including definitions, determinations and calculations for the analytical performance parameters, together with densitograms.
6. Proposed criteria for system suitability test.
7. Methods reported as properly written SOPs in detail.
8. Detailed evaluation of the test method validation procedures containing all of the recommendations and precautions to be taken into consideration when the TLC method is being routinely used; some recommendations should be given as to when and why revalidation might be necessary.

7 METHOD DEVELOPMENT

Method development, which results in sufficient separation, is one of the most critical steps of qualitative and quantitative planar chromatography. The main steps involved in method development of HPTLC for pharmaceutical analysis are:

1. selection of the stationary phase
2. selection of the vapor phase
3. selection of suitable solvents
4. optimization of the mobile phase
5. selection of the development mode.

7.1 Selection of the Stationary Phase

Silica gel is the most widely used stationary phase for pharmaceutical analysis. Modified and chemically bonded phases are also used. Practically all stationary phases used in normal-phase and reversed-phase HPLC are now available for TLC.

Precoated TLC or HPTLC plates 20×20 cm in size with aluminum or polyester supports are usually employed, mainly for economic reasons. These plates can be cut to size and shape to spot a particular analyte using scissors. Prewashing of chromatographic plates is an essential step. After washing, the plates must be dried for a sufficient time to ensure complete removal of washing liquids in a drying cupboard, by keeping them between two blank glass plates. The washed plates should always be stored in a dust-free atmosphere under ambient conditions, preferably in desiccators without the use of grease for sealing and any drying agents. Prewashing of plates must be done to at least 1–2 cm longer than the subsequent chromatographic development so that any dirt accumulated at the front does not interfere with the densitometric scanning. Methanol is the most commonly used prewashing solvent. Mixtures of chloroform in methanol (1 : 1), ethyl acetate in methanol (1 : 1), and chloroform–methanol–ammonia (90 : 10 : 1) have also been used as solvents for prewashing. Methylene chloride–methanol (1 : 1) is best suited for removing impurities picked up during storage in the laboratory. One may also use 1% ammonia or 1% acetic acid in methanol for prewashing.

7.2 Selection of the Vapor Phase

Selection of the vapor phase is a variable offered in planar chromatography. The type of chamber used decides the vapor phase. Basically there are two types of chamber. In normal (N) chambers there is a distance of more than 3 mm between the layer and the wall or between the layer and the lid of the chamber in the horizontal development of the chromatographic tank. If this distance is smaller the chamber is said to have the sandwich (S) configuration. For saturated and unsaturated systems both these chambers can be used. Characterization of the chamber saturation is done by the marker dye test, as proposed by Nyiredy et al.[64] The time required for chamber saturation depends upon the nature and composition of the mobile phase and layer thickness. When dealing with solvents of low polarity, such as aliphatic hydrocarbons, toluene, and their mixtures, preloading of the dry layer with solvent vapors should be avoided. However, preequilibrium is often recommended for high-polarity solvents such as methanol. Development in a nonsaturated or partially saturated atmosphere is recommended with solvents used in a composition leading to phase separation, such as mixtures of *n*-butanol, water, and glacial acetic acid. However, in the case of reversed-phase thin-layer chromatography (RPTLC) it is always preferable to saturate the chamber with methanol. If chromatographic separation is to be carried out at a controlled relative humidity of the chamber, then a suitable liquid is placed in a separate device prior to inserting the plate in the tank. The relative humidity of the room is usually controlled by a dehumidifier. However, if experiments are to be carried out at specific relative humidity, then a solution of sulfuric acid or salt solutions may be employed. Twin-trough chambers are suitable for all developing techniques and comparatively smaller volumes of the mobile phase are required.

7.3 Selection of Suitable Solvents for the Mobile Phase

The use of poor-grade solvents in preparing the mobile phases has been found to decrease the resolution, spot detection, and R_f reproducibility. The mobile phase composition is generally selected by a controlled process of trial and error, based on experience in the field. The mobile phase should be chosen taking into consideration the chemical properties of analytes and the sorbent layer. The basis of the strategy for solvent selection is the solvent classification by Snyder[65] who classified more than 80 solvents into eight groups for normal-phase chromatography according to their properties as proton acceptors, proton donors, and their dipole characteristics. From these eight groups 29 solvents were chosen which are called neat solvents and used in planar chromatography. An efficient method of screening a large number of neat solvents has been described by Birkinshaw and Waters.[66] With automatic CAMAG TLC Sampler III the same sample solution is applied spot-wise in a pattern on an HPTLC plate. Thereafter, 45 µL of different solvents are applied to the same positions at a high dosage rate (500 nL s^{-1}) so that circular chromatograms develop. From the position and sharpness of the fraction rings formed, conclusions can be drawn as to the suitability of the solvents. From the solvents showing good separation, their homologs or other solvents of the same group may be tested. Consequently the structure and the properties of the compounds to be separated do not have to be known for these experiments. After these experiments the solvents giving the most appropriate separations are chosen for further optimization of the mobile phase.

7.4 Optimization of the Mobile Phase

Mobile-phase composition is highly important in planar chromatography. Since the early days of chromatography considerable effort has been devoted to optimization because of the specific problems encountered in liquid chromatography. The widespread availability of computers has been of assistance for both liquid chromatography and TLC.[67,68] Optimizing the mobile-phase composition for HPTLC consists of four levels of operation.

7.4.1 First Level

Neat solvents from different selectivity areas are tested as described above for solvent selection. If acceptable resolution in the medium R_f range is achieved here, the operator can proceed directly to level three with these solvents, i.e. the investigation of solvent mixtures. If this is not the case, level two must be followed.

7.4.2 Second Level

Solvents that leave the main fractions near the start or move them close to the front need to be adjusted in strength. If the R_f values are too high, the solvent strength is decreased by adding *n*-hexane or toluene or, if they are too low, the solvent strength is increased by the addition of water, methanol, or ethanol, usually in the ratio of 9 : 1 or 8 : 2.

7.4.3 Third Level

At this level mixtures of solvents from different selectivity groups are investigated by adjusting strength, if required. These solvent mixtures can be binary, ternary, or even quaternary. It is best to start with the center and outside selectivities, i.e. using binary mixtures in the ratios 1 : 1, 9 : 1 and 1 : 9, or ternary mixtures in the ratios

1:1:1, 8:1:1, 1:8:1, and 1:1:8. At this (third) level addition of small amounts of acidic (acetic acid) or basic (triethylamine) modifier can be considered and tested whenever this appears promising. Also at this level, if not sooner, the operator should work with the developing device to be used later in routine analysis, such as twin-trough, horizontal, or automatic developing chamber.

7.4.4 Fourth Level

At this level final optimization of the mobile phase to be used for a particular separation is made. To obtain the best separation, small variations in the proportions of different solvents may be necessary.

Solvent selection based on experience and chromatographic intuition can be very time-consuming when applied to complex mixtures. For these, more systematic strategies have been elaborated:

- simplex method[69,70]
- prisma model method[71,72]
- window diagram method[73]
- overlapping resolution map method.[74,75]

7.5 Selection of the Development Mode

Ascending linear development is most frequently used for TLC. However, horizontal development has become more common in recent years. Circular development, where the solvent system migrates readily from the centre of the plate to the periphery, is well established for compounds in the lower R_f range.[76,77] The separation power of the circular development mode is greater than for the horizontal development mode. In the anticircular development mode the solvent system enters the layer at a circular line and flows towards the centre. As the solvent flow velocity decreases with the square of the distance, but the area wetted also decreases as the square of the distance travelled, the speed of the solvent system migration is practically constant. Therefore, this mode is the fastest with respect to separation distance. Anticircular development is a widely accepted approach in analytical TLC if the resolution must be increased within the higher R_f range.[21]

Of the multiple development techniques, unidimensional multiple development is effective to improve separation in lower R_f ranges; incremental multiple development improves the zone centre separation; gradient multiple development increases the separation capacity of the chromatographic system; bivariate multiple development is effective for samples of differing polarity. For mixtures of components spanning a wide retention range some form of gradient development is required to obtain even spacing of the developments in the chromatogram. The arrival of the automated multiple development chamber has done much to popularize gradient development in TLC. In a typical automated separation the chromatogram is developed repeatedly in the same direction with successive developments being over increasing migration distances; increments are generally between 1 and 5 mm and a complete program usually comprises 10–30 cycles. Between developments the solvent is drained from the chamber and the mobile phase contained in the layer is evaporated under vacuum. New solvent of any selected composition is then mixed and fed into the developing chamber and proceeds to ascend the layer. All steps are fully automated under capillary flow-controlled conditions – the useful plate length from a separation is limited to above 80 mm, whereas in an optimized separation typical zones have widths of 2–3 mm. Thus the separation capacity for baseline-resolved zones is 25–40, a considerable increase over the separation capacity obtained using conventional development modes.

8 COMPARISON WITH OTHER METHODS

Comparisons of TLC to other chromatographic methods have been reviewed.[78–84] TLC involves the concurrent processing of multiple samples and standards on an open layer developed by a mobile phase. Development is performed usually without pressure, in a variety of modes, including simple one-dimensional, multiple, circular, and multidimensional. The detection of the zones is done statistically with an assortment of diverse possibilities. Paper chromatography is fundamentally very similar to TLC, differing mainly in the nature of the stationary phase. TLC is superior to paper chromatography because it is faster, more efficient, and allows more versatility in the choice of stationary and mobile phases. HPTLC layers are smaller, contain known sorbents with smaller, more uniform particle size, are thinner, and are developed for shorter distances compared to TLC layers. These factors lead to faster separations, reduced zone diffusion, better separation efficiency, lower detection limits, less solvent consumption, and the ability to spot more samples per plate.

HPLC involves the elution under pressure of sequential samples in a closed on-line system with dynamic detection of solutes, usually by absorption. The predominant mode of HPLC is reversed phase on bonded silica columns, whereas in normal-phase TLC silica gel is most widely used. The reasons for this difference include the change in properties of silica gel columns caused by continuous mobile-phase flow (which is unimportant in silica gel layers because they are used only once), and the impracticability of using solvents with high percentages of water to develop many brands of bonded reversed-phase layers.

TLC is the most versatile and flexible chromatographic method for the separation of all types of organic and inorganic molecules that can be dissolved and are not volatile. It is rapid because precoated layers are usually used as received without preparation. Even though it is not fully automated like HPLC, TLC has the highest sample throughput because up to 30 individual samples and standards can be applied to a single plate and separated at the same time. The ability to separate samples simultaneously in parallel lanes in TLC is important in applications requiring high sample throughput such as screening of biological fluids for drugs, determining drug residues in animal products, study of drug impurity profiles, etc. Modern computer-controlled scanning instruments and automated sample application and developing instruments allow accuracy and precision in quantification that are in many cases equivalent to HPLC and GC. There is a wide choice of layers and developing solvents (acidic, basic, completely aqueous, aqueous–organic). Solvents that can cause interference with HPLC UV detection can be used in TLC because the mobile phase is removed from the plate prior to detection. Every sample is prepared on a fresh layer, so that problems involved with carryover and cross-examination of samples and sorbent regeneration procedures are avoided. Mobile-phase consumption is low, minimizing the costs of solvents and waste disposal. Because layers are not normally reused, sample preparation methods are less demanding and complex. Also, impure samples can be applied without concern for additional (ghost) peaks and for noneluting compounds that shorten the life of HPLC columns. The wide choice of development methods and pre- or postchromatographic detection reagents leads to unsurpassed specificity in TLC, and all components in every sample, including irreversibly sorbed substances, can be detected.

There is no need to rely on peaks drawn by a recorder or to worry about sample components possibly remaining uneluted on the layer. Being an off-line method, the various steps of the procedure are carried out independently. As an example of the advantage of this approach, zones can be scanned repeatedly with a densitometer using different parameters that are optimum for individual sample components. TLC and HPTLC are cost effective and environment friendly, and the chromatograms can be preserved as well as being photo- or videodocumented.

ACKNOWLEDGMENT

I am indebted to my research students who have helped me during the literature search and preparation of the manuscript.

The biopharmaceutical market has exploded in the last 10 years, with annual sales easily exceeding a billion dollars per year. Analysis and purification are essential components in the production of therapeutic proteins and peptides, and chromatography is at the core of all pharmaceutical separations. The more popular chromatographic techniques used in the purification of proteins and peptides are reversed-phase chromatography (RPC), hydrophobic interaction chromatography (HIC), ion-exchange chromatography (IEC), affinity chromatography (AC) and size-exclusion chromatography (SEC). In order to meet the challenges of the future it is essential to understand the fundamentals of each technique. In this article an overview of the more popular chromatographic techniques employed to purify biomolecules is presented. Relevant examples are also given and a discussion of detection and scale-up is provided.

1 INTRODUCTION

Downstream purification is an essential component of any chemical process. Products from industrial chemical, biochemical and biopharmaceutical processes all require a certain level of purity before they are commercially sold. Pharmaceutical products in particular must meet stringent purity requirements. Pharmaceutical production plants often rely on chromatography as an integral part of their purification procedures. With the advent of biopharmaceuticals, chromatography is being utilized as a means of purifying very complex biological mixtures containing therapeutic proteins and peptides. The intent of this article is to discuss the role of chromatography in biopharmaceutical processes. Before the discussion on chromatography begins, a brief introduction concerning the potential uses of proteins and peptides as therapeutic agents is presented.

Proteins and peptides manufactured by pharmaceutical companies are part of the ever-evolving biopharmaceutical arena. Simply put, biopharmaceuticals are drugs produced by genetically engineered microorganisms, transgenic animals or transgenic plants. These drugs are usually proteins or peptides. Proteins and peptides are large macromolecules that are responsible for performing very specific tasks in living organisms. The specific role of each molecule is dictated by the amino acid sequence. One example of this specificity can be seen in the digestive enzyme pepsin.[1] This protein is found in the intestinal mucosa of most animals. Pepsin has only one purpose and that is to fragment the proteins and peptides consumed with each meal. Pepsin cleaves each protein at the same location regardless of type. In principle if biopharmaceutical drugs can be developed and designed specifically to target complicated diseases such as AIDS (acquired immunodeficiency syndrome) or cancer, thousands if not millions of people will benefit.

The specificity of protein molecules has intrigued medical researchers for years. This is because the challenge in all pharmaceutical research is to develop medications that are specific enough to disable the infectious agent without harming the human host. In some cases the medical community has been very successful. An excellent example of this can be seen in the development of the smallpox vaccine. When the human body has been exposed to the vaccine the immune system produces very specific antibodies that are capable of protecting the host from a smallpox infection. Antibodies are simply protein molecules whose sole purpose is to protect the host from microbial or viral invaders. The introduction of this vaccine has greatly minimized the risk of this virus once again becoming rampant among the general

Encyclopedia of Analytical Chemistry

population. This approach cannot however be universally applied to other types of viral infection. An example of this is AIDS. Scientists have not yet found a nonvirulent form of the AIDS virus that can be used for vaccination purposes. A possible alternative route that can be used in fighting viruses like AIDS may potentially be found in a specific class of biopharmaceuticals called monoclonal antibodies (Mabs). Mabs are antibodies that have been specifically engineered to target specific types of foreign invaders.[2] For example if a certain species is immune to the AIDS virus, this means that this species must possess the ability to produce antibodies that are capable of neutralizing the virus. If this antibody can be identified, then perhaps genetically engineered microorganisms or transgenic animals can produce it. In principle, when Mabs are introduced to the human host they should protect the human in the same manner that they protect their natural host.

Researchers are also testing the effectiveness of biopharmaceuticals in the treatment of nonviral diseases such as cancer. Surgery, radiation and chemotherapy are three common approaches used to fight this disease. These techniques have helped many patients to extend their lifespan significantly; however, for some cancer patients radiation and chemotherapy produce extremely undesirable side effects. In some cases the chemotherapy and/or radiation do not stop or reverse the progress of the cancer. This has lead biopharmaceutical researchers to look for a better approach. One example of this can be seen in the ongoing research with endosatin and angiostatin.[2] These proteins are specifically designed to constrict the blood flow to cancerous tumors. These and other anticancer biopharmaceuticals are still under investigation. If they do prove to be effective in clinical trials, they should, in principle, produce little or no side effects because of the ''task specificity'' of protein molecules.

Still another example of the potential of biopharmaceuticals is gene therapy.[3] Gene therapy can be divided into two categories. The first category is somatic cell gene therapy, where the genetic components of certain cells are altered to assist the host in fighting off certain diseases. This alteration is not inheritable by the offspring of the host. The second category is germ line gene therapy, where the genetic material of a fertilized egg is altered. The offspring inheriting these genetic traits are permanently altered. The overall goal of gene therapy is to protect the host from monogenic diseases such as adenosine deaminase (ADA) deficiency, cystic fibrosis, Duchenne muscular dystrophy, polycystic kidney disease, melanoma, neuroblastoma, brain tumors, and many more.

The first biopharmaceutical drug approved by the FDA (Food and Drug Administration) was Humulin, which was developed by The Eli Lilly Company. FDA approval of this drug came in the mid-1970s, 15 years after the discovery of DNA. By 1987 four biopharmaceutical drugs were approved by the FDA, and by mid-1998 approximately 79 biopharmaceuticals were approved for use. Currently, biotech drugs generate over one billion dollars of revenue annually, and the figure is expected to rise sharply.[2]

The production of biopharmaceutical products is linked to the identification of specific genes or receptor sites and genetic engineering technology. Once the desired protein drug has been identified, it is up to the engineering and manufacturing community to produce this drug on a large scale. In a typical biotech process the desired protein is created by genetically engineered microorganisms. If the desired protein resides in the cytoplasm of the microorganism, the cells are ruptured to release the protein into solution. If the protein is soluble, the fermentation broth is filtered or centrifuged to remove excess cellular material. This is usually followed by an enrichment step that could typically involve membrane filtration or extraction. If the protein cannot be adequately purified by these techniques then chromatography is employed as the next step.

Chromatography is at the core of most analytical separations. It has been extensively used in the biotech industry for the purification of proteins and peptides. The popularity of chromatography can be attributed to the versatility of this technique. There are a number of stationary phases that can be commercially purchased. Each stationary phase has the ability to separate analytes by exploiting the differing affinities each analyte has for the immobilized ligands on the stationary phase surface. Additionally, the mobile phase composition and/or pH are key variables that can also be exploited to achieve the successful purification of the desired product.

In this article we will attempt to identify the chromatographic techniques employed in biopharmaceutical processes. Additionally, the use of detectors will be covered and issues relating to scale-up will also be discussed.

2 BACKGROUND

Proteins and peptides are composed of amino acids. The sequence of amino acids dictates the role of a given protein or peptide. In general a peptide has one specific amino acid sequence. A protein on the other hand may have multiple amino sequences and proteins may also possess inorganic compounds, such as iron in the case of hemoglobin. The physical configuration of proteins and peptides also depends on the amino acid sequence. In an aqueous environment each molecule is folded in a manner that forces a preponderance of hydrophobic amino acid

Figure 1 Generalized block diagram of recombinant DNA process. (Reproduced with permission from A. Sadana, in *Biopharm*, 26–33, March 1994,[3] Copyright by Advantstar Communications Inc. Advanstar Communications Inc. retains all rights to this article.)

groups to the interior of the molecule and hydrophilic amino acid groups to the exterior of the molecule. The activity of these macromolecules is highly dependent on the physical structure. When a protein or peptide loses its unique structure, it is considered denatured. From an engineering standpoint high temperature and excessive agitation can cause denaturation. Additionally, exposure to certain chemicals and harsh environments can trigger unfolding. An example of a harsh environment would be an environment in which the pH diminishes the activity of the protein. Thus it is essential that the production and purification process conditions be specified in such a way as to keep the structure of these molecules intact.

A general flowchart showing the production and purification of recombinant DNA proteins is shown in Figure 1.[4] The first step in this process is fermentation.

The desired protein manufactured by the cells is either contained internally within the cytoplasm or excreted through the cell wall. If the protein is excreted through the cell wall, the cell lysis (disruption) step is eliminated. Also the recovery of the protein becomes easier because the number of impurities in the bioreactor effluent is far fewer. Many bioprocesses do however require disruption. During cell disruption the desired protein is released into solution along with numerous other molecules that comprise the cell wall and internal structure. Ultrafiltration membranes remove many of the impurities released into solution by disruption. Since proteins are known to adsorb to hydrophobic materials, the membranes used in the clarification process should be hydrophilic in nature to minimize adsorption and permanent denaturation. The filtration process must remove as many impurities as possible. At this point in the process the composition of the solution must be known because chromatography is generally the next step. Accurate knowledge of the feed composition is essential in identifying the type of stationary phase and the operating conditions that are needed to achieve further product purity.

Figure 1 reveals that IEC, AC, HIC and gel filtration chromatography (GFC) are the popular chromatographic options for protein purification. IEC is an obvious choice because proteins are charged molecules and IEC exploits differences in charge to purify biomolecules. HIC exploits differences in the hydrophobicity of proteins. The speed and resolution of this technique is comparable to IEC and SEC. HIC also has additional benefits in that it can remove endotoxins, nucleic acids and viruses from the sample matrix.[5] AC utilizes highly specific immobilized ligands on the stationary phase. These ligands attract molecules possessing similar or complementary moieties. Finally GFC separates proteins and peptides by their size. In GFC the smallest molecules exit the column last and the largest molecules exit the column first.

An example of a plasmid DNA process[6] is shown in Figure 2. This figure again shows chromatography as an integral part of the purification process. In this case the stationary phase will either be an anion-exchange resin or a size-exclusion gel. The selection of the stationary phase generally depends on the nature of the impurities. If some form of adsorptive chromatography is used, it is generally desirable to have the product as the most strongly adsorbed component.[3] With this strategy the impurities will exit the column first. If SEC is used, it is essential that the size differences between the product and the impurities be large enough to achieve a good separation. As previously stated, it is preferable for the desired product to be the most strongly adsorbed. Under this scenario the desired product can be captured with minimal risk of contamination. If the desired product is not the strongest adsorbing analyte then the process designer must ensure that there is adequate resolution between the product and the leading and trailing impurities. A schematic flow sheet of a chromatographic unit operation[7] is shown in Figure 3. It is evident from this diagram that the operator and/or the control system must be aware of everything that is flowing through the system. It is also apparent that good resolution is essential to minimize contamination and maximize yield. The actual time the product tank inlet valve is opened and the amount of time this valve stays open is highly dependent upon the resolution that is achieved by the column.

The heart of the system shown in Figure 3 is the column. The proper selection of the column stationary phase is vital. The selection of the mobile phase can also influence the separation, but the stationary phase undoubtedly has a large effect on the separation. The chromatographic designer must look for physical parameters that distinguish between the product and the impurities. As previously stated, molecular size difference is often used as a means of purifying proteins and peptides. In many other cases molecular charge differences can be exploited, while in other applications differences in solubility and/or hydrophobicity are used to achieve a separation. Affinity can also provide an effective means of achieving purity. One method by which chromatographic designers can explore these physical differences is by collecting capacity factor data for the product and each impurity in the sample matrix. The stationary phase that provides the greatest differential between the product capacity factor and the capacity factors for the impurities is normally chosen for plant operations. Another way of obtaining the same data is to produce pure component isotherms. The quantity of material required for these experiments may be an issue; however, it is important to note that isotherm data are critical because the capacity factor approach is not adequate when the chromatographic system is overloaded, as is the case in many pharmaceutical applications. Components with the greatest attraction for the stationary phase will also have the highest loading. The stationary phase that demonstrates the greatest differential between the product loading and impurity loading will normally be chosen for plant operations. The former method is currently the most popular, because correlations have been developed that relate the capacity factor to peak resolution. These correlations also allow designers to estimate column length for scale-up.

An overview of the various stages of protein fractionation is shown in Table 1.[8] In the initial fractionation step the main goal is to capture and concentrate similar

species into groups. The goal of intermediate fractionation is to separate the components that were concentrated into groups in the initial stage. The final stage is polishing. The goal here is to attain the required purity as specified by the FDA. As seen in Table 1, the various modes of chromatography that are commonly employed in protein and peptide purification are reversed phase, hydrophobic interaction, ion exchange, affinity and size exclusion. These techniques that are used to purify peptides and proteins in pharmaceutical applications will be discussed in the next sections. Because of the competitive nature of the pharmaceutical business, pharmaceutical companies rarely publish articles describing their process capabilities. Therefore the examples cited in this article come from research articles that have been published in key scientific journals.

3 APPLICATIONS

3.1 Reversed-phase Chromatography

RPC is the most popular form of chromatography used in the purification of pharmaceuticals. The popularity of this technique is due to its flexibility. In RPC the column is packed with a nonpolar stationary phase. The solute is brought into contact with the stationary phase by a polar mobile phase and is eventually displaced from the stationary phase with a suitable solvent. The main role of RPC in the biopharmaceutical industry is in the purification of polypeptide mixtures. RPC is well suited to handle very complex mixtures of polypeptides. This is because a number of parameters such as pH, temperature, mobile phase composition and solvent gradient can all be adjusted to obtain the desired product in a highly purified state. This type of flexibility underscores the popularity of this technique.

The separation of components in RPC is primarily achieved by differences in solute hydrophobicity and solubility. The mobile phase is usually an aqueous buffer that contains ion-pairing agents such as trifluoroacetic acid (TFA). In most applications the ion-pairing agent is added to buffer in low concentrations to assist in solubilizing hydrophobic macromolecules such as large polypeptides. The stationary phase in many RPC applications usually contains *n*-octadecyl, *n*-octyl or *n*-butyl moieties bonded to the support. These stationary phases are all hydrophobic in nature with *n*-octadecyl being the most hydrophobic and *n*-butyl being the least hydrophobic. The particles comprising the stationary phase are highly porous. The average particle diameter ranges from approximately 3 μm for analytical columns to 100 μm for preparative columns. A summary of common RPC stationary phases[9] is presented in Figure 4.

The elution of analytes in RPC is accomplished by adding an organic modifier to the mobile phase. Typical organic modifiers that are commonly used are acetonitrile, isopropanol, ethanol and methanol. The solubility of each analyte in the ''eluting'' mobile phase is also a key factor because the elution order of each analyte is a function of the mobile phase solvent strength. The solvent strength of the mobile phase depends on the type and concentration of the organic modifier used. In a typical application, analytes are desorbed from the stationary phase by a linear gradient in which the concentration of the organic modifier is linearly increased. When the concentration of the organic modifier reaches a certain level the analyte's affinity for the mobile phase becomes greater than its affinity for the stationary phase. In other words when the solvent strength reaches a certain level it is thermodynamically more favorable for the analyte to be in the mobile phase than adsorbed to the surface phase. Therefore subtle differences in solubility can be exploited to provide adequate separation and purification of sample mixtures.

A number of mathematical models describing RPC have been published. Among the most common are the solvaphobic theory[10] and the stoichiometric displacement model (SDM).[11] A detailed description of each theory is beyond the scope of this chapter and the reader is

Figure 4 Examples of RPC stationary phases. (Reproduced by permission of Wiley-VCH, a subsidiary of John Wiley & Sons, Inc., from Uwe D. Neue, *HPLC Columns*, 1997,[9] Copyright Wiley-VCH, 1997.)

referred to the references cited for a detailed description. It is however useful to outline the simplest of these models briefly, the SDM. This model is based on the premise that when a solvated molecule is adsorbed by the adsorbent, a stoichiometric number (Z) of solvent molecules are released at the interface between the adsorbent and the solute. This SDM equation for the equilibrium constant (K) in RPC is shown in Equation (1):

$$K = \frac{P_b[D_o]^z}{P_m[L_d]^n} \tag{1}$$

where P_b and P_m are the adsorbed protein concentration and unbound protein concentration, respectively, D_o is the solvent concentration and L_d is the ligand density. The reported expression for the capacity factor is (Equation 2):

$$\log k' = z \log \frac{1}{D_o} + \log[I] \tag{2}$$

where $I = ([L_d]^n \phi K)/[D_o]^z$ and ϕ is the phase ratio. If the ligand density and phase ratio are known, the equilibrium constant can be calculated directly. Once K is known, the linear region of the isotherm can be approximated from Equation (2). In order to approximate the nonlinear portion of the isotherm, activity coefficient data are needed.

Although RPC is widely used in the pharmaceutical industry, it is only used in limited applications for the purification of therapeutic proteins. Typical biopharmaceutical applications that are amenable to RPC are the purification of polypeptides and small proteins that tend to be mildly hydrophobic in nature. The limitations are primarily due to the problem of denaturation. Proteins and certain polypeptides have unique three-dimensional structures. When proteins with strong hydrophobic interiors are brought into contact with a strongly hydrophobic stationary phase, the protein will rearrange its structure to allow the hydrophobic interior to have maximum exposure to the surface. If the hydrophobic patches have a strong affinity for the stationary phase, irreversible adsorption can sometimes occur. If irreversible adsorption does not occur some proteins can still be permanently denatured. In either case, these effects lead to low recoveries or insufficient purification (mixture of active and denatured protein). Insufficient purification is usually denoted by the presence of very broad peaks in the chromatogram.

An example of the effect of protein hydrophobicity in RPC[12] is seen in Figure 5. In this figure the chromatograms of three different proteins of increasing hydrophobicity from (a) to (c) are presented. These results were obtained using 5-μm C_4-silica particles in a 250×4.6-mm internal diameter (ID) column. The least hydrophobic protein, ribonuclease A, is shown in Figure 5(a). This chromatogram is described as being ''good''. This is because of the symmetrical shape of the peak and a recovery that exceeds 80%. Figure 5(b), which is labeled ''bad'', is for alcohol dehydrogenase. This peak may indicate conformational changes and is labeled ''bad'' because in this application wide protein peaks in RPC are usually the result of conformational changes. Figure 5(c) is β-galactosidase. The peak shape for this protein is labeled ''ugly'' because it is extremely broad with multiple bands present.

The hydrophobicity of 33 example proteins and peptides[12] is presented in Table 2. This table indicates the appearance of a relationship between the hydrophobicity of a protein and the quality of the RPC chromatogram. Some exceptions to this general relationship are also apparent. For example carbonic anhydrase (hydrophobicity = 129) yields a good chromatogram while β-lactoglobulin (hydrophobicity = 127) yields a bad chromatogram. Perhaps an interesting experiment would be to rank the peak shapes against their heats of adsorption. This type of experiment could possibly explain these inconsistencies.

Figure 5 Peak shape as a function of protein hydrophobicity. (Reprinted from W.G. Burton K.D. Nugent, T.K. Slattery, B.R. Summers, 'Separation of Proteins by Reversed-phase High-performance Liquid Chromatography: 1. Optimizing the Column', *J. Chromatogr.*, **443**, 363–379, 1988,[12] Copyright 1988, with permission from Elsevier Science.)

A good example of the ability RPC has in resolving polypeptide mixtures is shown in Figure 6.[13] One of the objectives of this work was to determine if reversed-phase high-performance liquid chromatography (RPHPLC) could be used in identifying polypeptide variants in hemoglobin. Hemoglobin has six polypeptide chains. The chromatograph of normal polypeptide chains in hemoglobin is shown in Figure 6. Figure 7 shows the chromatograms of individuals with variant β-chains. This example plus others reported by Huisman[13] indicate the utility and reliability of RPHPLC. This method cannot however be used to predict which mutant is present although it can nonetheless indicate the presence of an abnormality.

Another example of the ability of RPHPLC to resolve polypeptide mixtures is shown in Figure 8,[14] for the separation of human growth hormone variants. The results here demonstrate the previously mentioned effect of solubility on resolution. Each variant (a, b and c) had slightly different solubility in the mobile phase solvent. The difference, although very slight, was significant enough to be amplified by RPC.

The separation of five peptides ranging in size from 2 to 14 amino acid residues is shown in Figure 9.[15] Unlike the previous two examples these peptides were eluted under isocratic conditions using a phosphoric acid buffer at pH 3. Isocratic conditions indicate that the mobile phase composition is constant. Under isocratic conditions the separation is dependent upon the difference in the distribution coefficients for each analyte. Additional examples of protein and peptide purification with RPC can be found in the work of several authors.[16–25] Additional information and references discussing the use of RPC in purifying proteins and peptides can be found in Aguilar and Hearn.[26]

3.2 Hydrophobic Interaction Chromatography

HIC has become a popular technique used in the purification of proteins. HIC separates sample components by exploiting differences in hydrophobicity. This is the same principle employed by RPC; however, there are some significant differences. The first difference is that HIC usually takes place in the presence of salt. Solvents such as organic modifiers are not commonly used. The second difference is that the stationary phases in HIC are not as hydrophobic as in RPC. The ligand density is lower[27,28] and the molecular structures of HIC ligands are slightly different.[5,9] Since the hydrophobicity of the stationary phase is lower, the risk of protein denaturation is also lower. This reduction in hydrophobicity also reduces (not eliminates) the affinity of the protein for the stationary phase. This phenomenon has been in evidence in studies focusing on the energetics of adsorption.[29,30] In these experiments it was shown that the ΔH value associated with the adsorption of proteins on reversed-phase supports is exothermic. This is indicative of the fact that proteins, in particular the more hydrophobic proteins, will have stronger affinities for the stationary phase. This also explains why certain proteins irreversibly adsorb to reversed-phase supports. It is simply more energetically favorable for the protein to remain on the surface than to become solubilized in the mobile phase solvent. Similar studies were also conducted on hydrophobic stationary phases.[31–33] The results revealed that in this case of HIC protein adsorption was entropically driven. The reported ΔH values associated with adsorption were endothermic. From the standpoint of energetics, HIC appears to be a milder process. This milder nature may be the underlying reason why HIC is generally better suited to protein purification than RPC.

In HIC, protein elutions are usually accomplished through linear salt concentration gradients. The presence of salt has a great influence on the equilibrium behavior

Table 2 Hydrophobicity ranking of 33 proteins: characteristics and classification of protein standards[a]

in HIC. It has been postulated that the equilibrium distribution in HIC is a function of the preferential interactions between the protein, the salt and the water.[(34)] The free energy of a dissolved protein will increase when a salt such as NaCl is added to the solution. As a result of the presence of salt the protein will become preferentially hydrated; hydration excludes salt from the immediate vicinity of the protein. As the salt concentration is increased, the interactions between the protein and salt will also increase. This is because at higher salt concentrations the salt molecules displace some of the water molecules surrounding the protein. The protein, in an effort to reduce its free energy, will adsorb to the surface. The free energy of the protein is effectively reduced because the amount of protein surface area exposed to the salt has been minimized.

The selection of salt is an important decision in HIC separations. This is because the salt will alter the surface tension of water. If the surface tension of water is too high the protein will precipitate out. Once again the underlying reason for this is energetics. The free energy of the protein in the solid phase is lower because the protein–salt interactions are minimized when the protein has precipitated out of solution. A list of the common salts used in HIC[(35)] with their effects on the surface tension of water is presented in Table 3.

Figure 6 Chromatogram of normal polypeptide chains in hemoglobin. Column dimensions: 300 × 4.6-mm ID. Column stationary phase: Vydac C4 RP (Separations Group, Hesperia, CA, USA); Developer A: 80% water, 20% acetonitrile (CAN) and 0.1% TFA. Developer B: 40% water, 60% CAN and 0.1% TFA. Elution was accomplished by reducing developer A from 51% to 40% over 50 min. This step was followed by a further reduction in developer A from 40% to 20% over 40 min. The column was then purged with developer B for 10 min and equilibrated with 51% developer A. The flow rate was 1.0 mL min^{-1}. (Reprinted from T.H.J. Huisman, 'High Performance Liquid Chromatographic Analysis of Human Hemoglobins and Their Polypeptide Chains: Its Use in the Identification of Variants', *Anal. Chim. Acta*, **352**, 187–200, 1997,[13] Copyright 1997, with permission from Elsevier Science.)

The selection of the stationary phase is also another very important consideration. Although HIC is milder than RPC, protein conformation changes are still possible.[36] With this in mind, the system designer must carefully analyze the peak shapes of the purified analyte in question. If split peaks are present then a conformational change has occurred. If broad peaks are present then the possibility of a conformational change exists. The word ''possibility'' is used because broad peaks can also arise from excessive protein interactions with the stationary phase. If the desired protein has undergone a conformational change then the resulting effect will be a lower recovery. Examples of commercially available HIC stationary phases[5] are presented in Figure 10. Additional examples can be found in Neue.[9]

As previously stated, the speed and resolution of HIC are comparable with IEC. HIC is also advantageous because of its ability to remove endotoxins, nucleic acids and viruses from certain samples.[5] Also, as previously mentioned, the risk of denaturation is much smaller than RPC, and the use of harsh solvents for the purposes of elution are generally not required for most HIC applications.

A number of models describing HIC have also been published.[37,38] One such model is the preferential

interaction analysis model.[38] A summary of this model is presented in this section; however, a more thorough discussion can be found in Perkins et al.[38] This model focuses on the influence of salt on the equilibrium constant. Preferential interaction analysis has been used to study protein stabilization and precipitation. If the adsorption process in HIC is described by the stoichiometric Equation (3):

$$p\mathrm{P} + s\mathrm{S} \Longleftrightarrow c\mathrm{C} \tag{3}$$

where P is the protein, S is the surface site and C is the protein–ligand complex, and the variables p, s and c represent the number of water molecules associated with each entity in the equation, then the equilibrium constant for this process can be formulated as Equation (4):

$$\ln K_{\mathrm{obs}} = c\ln(m_{\mathrm{C}}) - p\ln(m_{\mathrm{P}}) - s\ln(m_{\mathrm{S}}) \tag{4}$$

where m represents the molal quantities of P, S and C. From the preferential interaction model, the equilibrium can be defined by Equation (5):

$$\left(\frac{\partial \ln(k')}{\partial \ln(m_3)}\right)_{T,P} = \frac{\Delta v_+ + \Delta v_-}{g} - \frac{n\Delta v_1}{m_1 g} m_3 \tag{5}$$

where Δv_1 is the net displacement of water molecules, $(\Delta v_+ + \Delta v_-)$ is the net change in modulator ions, m_3 is the modulator concentration, m_1 is the water concentration, n is the total number of cations and anions per formula unit, and g is the change in the $\ln(m_3)$ per change in the $\ln(a_3)$, where a is the activity of the modulator. Integration of Equation (5) leads to Equation (6):

$$\ln(k') = c + \left(\frac{\Delta v_+ + \Delta v_-}{g} - \frac{n\Delta v_1}{m_1 g}\right) m_3 \tag{6}$$

where c is an integration constant. From this model the number of displaced water molecules can be calculated. From these data an estimate of the required area for one protein molecule to adsorb on a given surface at a given modulator concentration can be made. This may provide a potential insight into determining the

Figure 10 Examples of HIC stationary phases. (a) Acetamide bonded phase, (b) methylether bonded phase, (c) ethylether bonded phase. (Reproduced by permission of Wiley-VCH, a subsidiary of John Wiley & Sons, Inc., from Uwe D. Neue, *HPLC Columns*, 1997,[9] Copyright Wiley-VCH, 1997.)

degree to which conformation changes are occurring. Once these data have been collected under certain conditions, they can then be used to estimate retention and changes in retention with respect to changes in modulator concentration.

An example of the resolving power of HIC is presented in Figure 11,[39] which shows the separation of two RNase variants. These variants were produced by deamination at position 67 of RNase. One derivative contained ASP (aspartyl) and the other iso-ASP. As seen in Figure 11, these molecules were eluted with a linear gradient that effectively lowered the salt concentration. As previously stated, lowering the salt concentration will lower the surface tension of the water. The surface tension is eventually lowered to a point where it becomes energetically favorable for the protein to interact with the water molecules rather than the surface.

Another example of protein purification using HIC is presented in Figure 12.[40] These results were collected on an HIC monolith column. The advantage of a monolith is that the contact surface area of the stationary phase is significantly increased. Figure 12 shows that all of the components were resolved in less than 4 min. This separation was carried out in a 50 × 8-mm ID column. The effect of salt on the system is the same as described in the previous example.

Figure 11 Separation of two RNase variants. Column: Spherogel HIC-CAA column (Beckman) equilibrated in 70% buffer A (3 M ammonium sulfate, 0.5 M ammonium acetate, pH 6.0) and 30% buffer B (0.5 M ammonium acetate, pH 6.0). Elution was carried out by increasing the concentration of buffer B from 30 to 70% in 10 min at a flow rate of 1.0 mL min^{-1}. (Reprinted with permission from A. Di Donato, M.A. Ciardiello, M. de Nigris, R. Piccoli, L. Mazzarella, G. D'Alessio, *J. Biol. Chem.*, **268**(7), 4745–4751, 1993,[39] Copyright the American Society for Biochemistry and Molecular Biology.)

Figure 12 Protein purification using an HIC monolith column. Column dimensions: 50 × 8-mm ID; column stationary phase: rigid porous polyacrylamide monolith; mobile phase: 10% butyl methacrylate; elution: linear gradient that steadily reduced the salt concentration in the mobile phase from 1.5 to 0.1 M ammonium sulfate in 0.01 M sodium phosphate buffer (pH 7) in 3.3 min; flow rate: 3.3 mL min^{-1}. The proteins shown in this chromatogram are cytochrome c (1), ribonuclease (2), carbonic anhydrase (3), lysozyme (4), and chymotrypsinogen (5). (Reprinted from Xie et al., 'Rigid Porous Polyacrylamide-based Monolithic Columns Containing Butyl Methacrylate as a Separation Medium for the Rapid Hydrophobic Interaction Chromatography of Proteins', *J. Chromatogr., A*, **775**, 65–72, 1997,[40] Copyright 1997, with permission from Elsevier Science.)

A third example showing the usefulness of HIC is shown in Figure 13(b). One of the three large peaks shown in Figure 13(b) is purified Mabs.[41] In this example the HIC column was preceded by an ion-exchange column. The chromatogram from the ion-exchange column is shown in Figure 13(a). The shaded area in Figure 13(a) gives the approximate location of the Mabs. Ion-exchange column fractions from 18–24 min were collected and injected into the HIC column. This produced the chromatogram shown in Figure 13(b); the shaded portion indicates the location of the purified Mabs. At the time this experiment was performed, the accepted way of purifying Mabs was by precipitation induced by the presence of ammonium sulfate. The disadvantage of precipitation is that a portion of the protein is normally lost. This experiment demonstrated the use of chromatography as a viable means of purification with minimal losses in protein activity. Additional examples of the resolving power of HIC can be found in the work of several authors.[42–46] Additional references and information on the use of HIC in the purification of proteins can be found in Cooke et al.[28] and Shansky et al.[35]

3.3 Ion-exchange Chromatography

IEC is the most common technique employed for protein purification. IEC exploits differences in protein charge

Figure 13 Separation of Mabs using IEC and HIC. The chromatogram of the ion-exchange column is shown in (a). The shaded area in (a) represents the approximate location of the Mabs. An aliquot from the ion-exchange column fractions from 18–24 min was injected into the HIC column producing the chromatogram shown in (b). The shaded area in (b) represents the location of the Mabs. HIC column dimensions: 75 × 7.5-mm ID; HIC stationary phase: TSK gel Phenyl 5 PW. HIC column equilibration: buffered solution containing 0.030 mol L^{-1} Tris-HCl and 1.0 mol L^{-1} sodium sulfate (pH 7.5). Elution was accomplished by reducing the ionic strength and the polarity of the mobile phase with a linear gradient for 80 min. The final salt concentration was 0 mol L^{-1} and the mobile phase contained 5% 2-propanol. The flow rate was 1 mL min^{-1}. The sample load was approximately 0.3 mg of protein. (Reprinted from B. Pavlu, U. Johansson, C. Nyulen, A. Wichman, 'Rapid Purification of Monoclonal Antibodies by High Performance Liquid Chromatography', *J. Chromatogr.*, **359**, 449–460, 1986,[41] with permission from Elsevier Science.)

to purify mixtures. Proteins are essentially very large electrolytes. Adjusting the solution pH to a value that is different from the protein's pI (the pH at which the protein is neutral) can alter the charge of a protein molecule. If the solution pH is above the pI of the protein, the protein will possess a net negative charge. Likewise the protein will possess a net positive charge when the solution pH is less than the pI. In IEC the stationary phase will have the opposite polarity of the desired protein. In general a weakly charged protein sample will require a strongly charged stationary phase to resolve the mixture. Strongly charged protein samples will usually require a weakly charged stationary phase to resolve the mixture. If a strongly charged molecule is brought into contact with a strongly charged stationary phase, the molecule could be irreversibly adsorbed. If the proteins and the stationary phase are too weakly charged, sample resolution will not occur. It should be noted that protein adsorption in IEC can be enthalpically or entropically driven. The ΔH of adsorption depends on the pH, the salt concentration and the stationary phase.[47–50] Thus it is possible to adsorb a protein with a net positive charge on an anion-exchange column, if the conditions selected result in an entropically driven process.

Like HIC, ion-exchange separations take place in the presence of aqueous buffers and salt. Buffers are important because their presence stabilizes the mobile phase pH. The choice of a buffer usually depends on the operating pH. Ideally, the pK_a of the buffer should be as close to the operating pH as possible. Some typical IEC buffers are found in the *Pharmacia Biodirectory*.[51] The presence of salt does however serve a different purpose in IEC. The salt acts as a displacing agent in IEC. For example in the case of an anion-exchange column the salt anions exchange with negatively charged proteins on the surface. In IEC the stationary phase, solution pH, column temperature and salt concentration are key design parameters. Some typical ion-exchange stationary phases are shown in Table 4.[52]

The stoichiometric equation describing the ion-exchange process is shown in Equation (7):

$$Z_n C_p + Z_p N_n \Longleftrightarrow Z_n N_p + Z_p C_n \qquad (7)$$

where C_p and N_p are the protein concentrations in solution and on the surface respectively. C_n and N_n are the respective concentrations of the salt counterion in solution and salt counterion on the surface. Z_p is the effective protein charge, and Z_n is the charge of the salt counterion.

Table 4 Examples of IEC stationary phases

Group	pH range	Structure
Anion exchangers		
Q (Quaternary ammonium)	2–12	$-CH_2-N^+(CH_3)_2-CH_3$
DEAE (Diethylaminoethyl)	2–9	$-O-CH_2-CH_2-NH^+(C_2H_5)_2$
QAE (Quaternary aminoethyl)	2–12	$-O-(CH_2)_2-N^+(C_2H_5)_2-CH_2-CHOH-CH_3$
Cation exchangers		
SP (Sulfopropyl)	2–12	$-(CH_2)_2-CH_2-SO_3^-$
S (Methyl sulfonate)	2–12	$-CH_2-SO_3^-$
CM (Carboxymethyl)	6–11	$-O-CH_2-COO^-$

[a] Reproduced by permission of Humana Press Inc., from D. Sheehan, R. FitzGerald, in *Protein Purification Protocols*, 1996.[52]

A thermodynamically consistent model that has been developed to describe the equilibrium relationship in Equation (7) is the nonideal surface solution (NISS) model.[53] The NISS equilibrium constant is defined by Equation (8):

$$K = \frac{a_p^s}{a_p} \left(\frac{a_n}{a_n^s}\right)^{\frac{z_p}{z_n}} \tag{8}$$

where a_p^s and a_p are the respective activities of the protein on the surface and in solution. a_n^s and a_n are the respective activities of the modulator on the surface and in solution. The activity of each species on the surface is defined as the product of $\gamma_i x_i$, where i represents either the protein or counterion on the surface, γ is the activity coefficient and x is the mole fraction. The activity of the adsorbed species has been calculated using a model developed by Talu and Zweibel.[54] From Equation (8) an expression for the capacity factor was derived and Equation (9) results.

$$\ln k' = \ln[K\lambda\phi] - \frac{z_p}{z_n}[\gamma c_n] \tag{9}$$

where K is the equilibration constant, λ is ion-exchange capacity of the resin, ϕ is the phase ratio, z_p is the protein charge, z_n is charge of the counterion, c_n is modulator concentration, and γ is the salt activity coefficient. If the resin capacity and phase ratio are known then Equation (9) can be used the calculate the equilibrium constant K and the protein charge z_p.

An example of IEC is presented[55] in Figure 14. In this work 11 egg-white proteins are separated by three methods. The known proteins in egg white are shown in Table 5.[55] The conclusions reached from this experiment were that IEC offered a more complete analysis when compared to RPC or gel permeation chromatography.

Another example of the resolving power of IEC is seen in Figure 15,[56] which shows the separation of six isoforms of ovalbumin using displacement chromatography. In displacement chromatography, the solutes are allowed to adsorb to the stationary phase. The solutes are then displaced from the adsorbent by a displacer, which has a higher affinity for the adsorbent than any of the solutes. This separation exemplifies the enhanced resolution potential that displacement chromatography possesses. An elution separation of the same mixture gave only three isoforms, but six were identified with displacement chromatography. Figure 15 illustrates an additional feature of ion-exchange displacement chromatography. All the isoforms are produced at concentrations substantially higher than the feed. The displacement process leads to concentration as well as separation of the sample components. Additional examples of IEC can be found.[57–66]

3.4 Affinity Chromatography

An excellent review of AC is presented by Subramanian[67] and highlights are presented in this section. AC is by far the most specific method that can be employed for the isolation of protein molecules. In RPC, HIC and IEC the adsorption process is consistent with the principles of physisorption. The interactions are not necessarily site specific, the heats of adsorption

Figure 14 Separation of hen egg-white proteins by (a) gel permeation chromatography, (b) reversed-phase chromatography and (c) ion-exchange chromatography. In this application the IEC column was reported to produce the best resolution. IEC column dimensions: 5 × 0.5-cm ID; IEC column stationary phase: Mono Q HR 5/5. The IEC column was equilibrated with 0.02 M Tris-HCl (pH 9.0). Elution of the protein from the IEC column was accomplished by a stepwise gradient that increased the concentration of NaCl. The flow rate was 1.0 mL min^{-1}. (Reprinted from A.C. Awade, T. Efstathiou, 'Comparison of Three Liquid Chromatographic Methods for Egg-white Protein Analysis', *J. Chromatogr., B*, **723**, 69–74, 1999,[55] with permission from Elsevier Science.)

are relatively low, and the process is usually rapid and reversible. In AC the interactions between the analytes and the surface ligands are extremely specific. In a more strict sense the interactions are site specific. This is because the stationary phase contains biospecific ligands that exclusively elicit very specific and limited types of interaction. The stationary phase ligands will only interact with specific groups on the protein molecule. This type of specificity is normally seen in chemisorption processes. Note that chemisorption is usually a slow process that takes place at elevated temperatures. In AC the process is usually rapid and typically occurs at ambient temperatures. This technique is used for the purification of highly valuable proteins. It is of particular value when the protein concentration is very dilute.

The principle underlying AC is shown in Figure 16. This emphasizes the biospecificity of the protein–ligand binding. Dilute protein solutions can be concentrated on the order of a 1000-fold. Interferon has been purified on an immobilized antibody column with a 5000-fold increase in specific activity. A list of the overall advantages and disadvantages of AC is shown in Table 6. Of the disadvantages listed, the slow adsorbent development time can potentially be the most difficult obstacle to overcome. This is due in part to the need for biospecific ligands. The search for biospecific ligands can be time-consuming and expensive. Once a ligand has been identified it must be attached to the support without losing its activity. Since proteins are large macromolecules the ligands must be spaced far enough apart to allow the protein–ligand complex to form. Finally, the stationary phase must be validated in a pharmaceutical plant.

Some examples of AC ligands and their target proteins are presented in Table 7. A critical parameter to consider in the selection of an AC ligand is the dissociation constant

Table 5 List of egg-white proteins[a]

Protein	Amount of total protein (%)	Mol. weight	pI
Ovalbumin	54	45 000	4.5
Ovotransferrin	12–13	77 700	6.0
Ovomucoid	11	28 000	4.1
Lysozyme	3.4–3.5	14 300	10.7
Ovomucin	1.5–3.5	$0.22–270 \times 10^6$	4.5–5.0
G2 ovoglobulin	1.0	47 000	4.9–5.3
G3 ovoglobulin	1.0	50 000	4.8
Ovoflavoprotein	0.8	32 000	4.0
Ovastatin	0.5	$7.6–9.0 \times 10^5$	4.5–4.7
Cystatin	0.05	12 000	5.1
Avidin	0.05	68 300	10.0
Thiamine-binding protein	Not determined	38 000	Not determined
Glutamyl aminopeptidase	Not determined	320 000	4.2
Minor Glycoprotein 1	Not determined	52 000	5.7
Minor Glycoprotein 2	Not determined	52 000	5.7

Figure 15 Separation of ovalbumin isoforms. Column dimensions: 250 × 4.6-mm ID. Column stationary phase: PAE 300 (Amicon). Mobile phase: histidine (pH 6.0); flow rate: 0.5 mL min^{-1}; regenerate: 0.1 M sodium citrate in 0.3 M sodium bicarbonate (pH 9); regenerant flow rate: 0.5 mL min^{-1}. (Reprinted from S.C.D. Jen, N.G. Pinto, 'Use of the Sodium Salt of Poly(vinylsulfonic acid) as a Low-molecular-weight Displacer for Protein Separations by Ion-exchange Displacement Chromatography', *J. Chromatogr.*, **519**, 87–98, 1990,[56] with permission from Elsevier Science.)

K_d, Equation (10)

$$K_d = \frac{[PL]}{[P][L]} \tag{10}$$

where PL is the protein–ligand complex concentration, P is the protein concentration and L is the ligand concentration.

The risks of irreversible protein adsorption and denaturation are minimized when the value of K_d is between 10^4 and 10^6. At higher K_d values the risk of protein damage increases. At lower K_d values the interaction between the protein and surface ligands may not be strong enough to retain the protein.

Once a protein is sufficiently bound to the stationary phase the column is then washed to remove excess debris. After washing, the protein is eluted from the column. Protein elution can be accomplished by varying pH, modulator concentration or possibly the concentration of a specific displacing cofactor or substrate. The latter two options can be cost prohibitive. If these options fail, then chaotropic agents such as urea or ethylene glycol can be used to desorb and elute the protein. It must be noted, however, that these chaotropic agents can be harsh and as a result some proteins can become denaturated.

An example of AC is shown in Figure 17,[68] which shows the purification of different types of blood cells. The stationary phase used was PEG 20M-sepharose 6B. The essential chemical structure of the stationary phase is shown in Figure 18. In all of the cases the adsorption of blood cells onto the stationary phase was induced by the presence of salt. This suggests that hydrophobic interactions may have played a key role in adsorption process. Additional information on AC can be found in Narayanan.[69] Additional examples of the resolving power of AC are given by various authors.[70–73]

3.5 Size-exclusion Chromatography

SEC, sometimes referred to as gel permeation, isolates proteins by using molecular characteristics such as size and/or shape. Molecules with similar molecular weight can be separated by shape or by significant conformational differences. In general the smaller molecules with high diffusivities permeate the matrix of the stationary phase

Figure 16 Overview of AC. (a) Sample is applied to the adsorbent, (b) target protein is bound to the ligand, (c) other proteins are washed away, (d) target protein is eluted from the adsorbent. (Reproduced by permission of VCH Publishers from G. Subramanian, *Process Scale Liquid Chromatography*, 1995.[67])

Table 6 Advantages and disadvantages of AC[a]

Advantages	Disadvantages
Overall process time may be rapid	Ligand may be expensive
Overall number of steps in a process are often reduced	Development of an adsorbent may be very slow
Capacity of the adsorbent can be high or low	Regeneration of an adsorbent can be difficult
Process is not limited be volume of sample	
Resolution can be very high

while the larger molecules with lower diffusivities tend to be carried through the column by the mobile phase. An overview of this mechanism[74] is shown in Figure 19. This technique is primarily used for desalting, buffer exchange and purification; however, it has also been used to isolate protein conformational changes that have been induced by a harsh solvent or by an extremely hydrophobic stationary phase. GFC can also be used to determine the molecular weight distribution of synthesized molecules.

SEC stationary phases are usually gels.[67] The gel matrix can be composed of individual polymer chains, aggregated polymer chains or combinations of both. Examples of the individual polymer gels would be the dextran and polyacrylamide gels. These gels have a protein exclusion limit of approximately 1×10^6 for globular proteins. If these gels are loosely cross-linked they tend to be mechanically weak. High-pressure applications could destroy the gel. For preparative applications the more tightly cross-linked gels provide the mechanical strength required for process applications. Agarose gels are an example of an aggregated polymer. Agarose has a high degree of cross-linking which gives it rigidity and mechanical strength. The composite gels are denoted by

Figure 17 Separation of blood cells. Column dimensions: 25 × 0.9-cm ID; column stationary phase: polyethylene glycol (PEG) 20M-sepharose 6B; eluent: 8% (w/w) dextran T40; mobile phase: 0.09 M sodium phosphate buffer at pH 7.4; flow rate: 4.4 mL h^{-1}. (Reprinted from Y. Shibusawa, 'Surface Affinity Chromatography of Human Peripheral Blood Cells', *J. Chromatogr., B*, **722**, 71–88, 1999,[68] with permission of Elsevier Science.)

Figure 19 Overview of SEC. In SEC smaller molecules with high diffusivities diffuse through the stationary phase while larger molecules with lower diffusivities are essentially carried through the column by the mobile phase. (Reproduced by permission of Academic Press, from G.K. Sofer, L.-E. Nystrom, *Process Chromatography: a Practical Guide*, 1989.[74])

their higher pressure limits across a wide fractionation range.

The choice of a stationary phase in SEC is usually driven by two factors. This first of these is the fractionation range of the proteins in question and the process conditions (pressure, sample load, flow rate, ... etc.). An example of a selection chart is shown in Figure 20.[74] Each solid line corresponds to a different stationary phase. Once the molecular weight of each component is known the distribution coefficient can be determined from the plot. The optimal stationary phase will be the one in which the distribution coefficients are significantly different.

An example of SEC is presented in Figure 21(a) and (b),[75] which show the effect of mobile phase flow rates and sample volume on resolution. As previously stated, one of the main uses of SEC is desalting. In all cases the salt was effectively removed from the sample components. This is because the salt molecules have a much higher diffusivity than that of the proteins. Figure 21 shows that desalting was less sensitive to the operating conditions, however, protein resolution was sensitive to increased flow rates and increased sample volumes. Additional information on SEC can be found in review articles cited in Irvine[76] and Barth et al.[77] Examples demonstrating the ability of SEC to purify biomolecules are given by several authors.[77–81]

3.6 Electrophoresis

Electrophoresis was originally developed for the separation of proteins. This technique is used extensively for protein purification on a small scale. Since electrophoresis is primarily limited to small-scale purifications, a brief overview is presented in this section. References are also presented for readers requiring additional information about this technique.

Protein separation takes place in a column with a diameter of 0.5 mm or less and in the presence of an electric field. In a typical application the electric field placed on the column is generated by a negatively charged anode at the inlet and a positively charged cathode at the exit. The degree of separation depends on the charge-to-mass ratio for each protein. The protein molecules with the greatest negative charge will have the highest affinity for the cathode provided that the relative difference in protein molecular weights is small. The positively charged anions will also move toward the cathode because the electroosmotic flow of the buffer is essentially carrying or pushing these molecules through the column. In capillary electrophoresis the mobility of each analyte is a key factor in determining the selectivity. The mobility (μ) of an analyte is related the electric field strength and the velocity by Equation (11):

Figure 21 SEC protein fractionation studies. Column dimensions: 250 × 9.4-mm ID; mobile phase of 200 mM sodium phosphate, pH 7.0. The flow rate varied from 0.25 to 5 mL min^{-1} in (a). The separation conditions and column were the same in (b) except that the flow rate was held constant at 2 mL min^{-1} and the injection volume was varied from 2 to 200 μL; 1, bovine serum albumin dimer; 2, bovine serum albumin; 3, ovalbumin; 4, lysozyme; 5, sodium azide. Results obtained by changing (a) flow rate and (b) sample size. (Reprinted from R.D. Ricker, L.A. Sandoval, 'Fast Reproducible Size-exclusion Chromatography of Biological Macromolecules', *J. Chromatogr., A*, **743**, 43–50, 1996,[75] with permission from Elsevier Science.)

$$v = \mu E \tag{11}$$

where v is the molecule velocity ($cm\,s^{-1}$), and E is the electric field strength ($V\,cm^{-1}$), and μ has units of ($cm^2\,s^{-1}\,V^{-1}$). The electric force F_e experienced by a given protein molecule is given by Equation (12):

$$F_e = qE \tag{12}$$

where q is the ion charge. The frictional force F_f for a spherical ion is given by Equation (13):

$$F_f = -6\pi\eta r v \tag{13}$$

where η is the solution viscosity and r is molecular radius. When these forces are balanced, Equation (14):

$$qE = 6\pi\eta r v \tag{14}$$

Solving for v and substituting the result into Equation (13) provides a theoretical prediction for the mobility in measurable terms,[82] Equation (15):

$$\mu = \frac{q}{6\pi\eta r v} \tag{15}$$

In Equation (15) the mobility is directly proportional to the molecular charge and inversely proportional to the molecular size and mobile phase viscosity. Since the net charge is a function of pH, the mobility of an ion is dependent upon the pH of the mobile phase.

A number of alternative versions[83] of electrophoresis are employed when the difference in protein mobilities is small. Isoelectric focusing is a form of electrophoresis that separates proteins by their pI values. A pH gradient is established in the column with a low pH at the inlet and higher pH at the outlet. Capillary gel electrophoresis separates proteins by size. A highly cross-linked polymer is present in the column. The separation is essentially the same as that employed by SEC. Micellar electrokinetic capillary chromatography is another technique commonly used. The method is good for separating proteins with similar charge. A micelle-forming surfactant such as sodium dodecyl sulfate is added to the mobile phase. The more hydrophobic proteins diffuse to the interior while the less hydrophobic proteins stay in the mobile phase. The proteins that diffuse into the micelle have effectively lowered their charge-to-mass ratio, thus reducing their mobilities. The less hydrophobic proteins emerge from the column first while those inside the micelles emerge last.

A thorough review of electrophoresis is presented by the work of several authors.[83–86] Examples of the resolving power of electrophoresis can be found in Jorgensen et al.[87] Rabel and Stobaugh,[88] and Dolink.[89]

4 DETECTION OF COLUMN RESPONSE

Detectors are an essential component of any chromatographic process. The output of a chromatographic detector displays a series of peaks that represent either a product or an impurity. Detectors are used in three different applications. These are manufacturing, design and research. In manufacturing, the detector is used to verify if the desired separation or purification of components was successful. In this application the chromatographer is looking for peak resolution. Good peak resolution means the product peaks should ideally be distinct with little or no overlap with other peaks representing impurities or other products.

The second application is in design. Before a column is specified for production a number of experiments are conducted to determine the proper stationary phase and mobile phase composition. The system designer uses data directly from the detector output to calculate peak resolution and the required number of theoretical plates. The resolution between any two peaks can be calculated by the empirical relationship shown by Equation (16):

$$R_s = \frac{1}{4}\frac{\alpha_1 - 1}{\alpha_1}\frac{k_1'}{1 + k_1'}N_1^{\frac{1}{2}} \tag{16}$$

where R_s is the resolution between component peak 1 and component peak 2, N_1 is the number of theoretical plates required for component 1 and k_1 is the capacity factor for component 1. α_1 is the ratio of k_1/k_2, where k_2 is the capacity factor for component 2. α is commonly referred to as the selectivity. N_1 can be further defined by Equation (17)

$$N_1 = \frac{L}{H} = 5.54\left(\frac{t_R}{W_{\frac{1}{2}}}\right)^2 \tag{17}$$

where L is the column length, H is the height equivalent of one theoretical plate, t_R is the retention time, and $W_{1/2}$ is the peak width in time units at half peak height. These two equations show that resolution is a function of peak shape and retention time. All of these data are taken from the detector output and used to specify the column and the method of achieving the desired separation or purification, thus making the detector a key part of the design phase.

In the third application, the detector output can be used as an investigative tool in analytical applications to explore the interaction between a given analyte and a given stationary phase. The peak shape reflects the nature of the interaction between an analyte and the surface. Broad peaks or peaks with long tails are indicative of strong affinities between the analyte and the stationary phase. They can also be indicative of mass

Figure 22 This demonstrates the effect of the isotherm on the component peak measured by the detector. (a) Linear isotherm, (b) Langmuir isotherm, (c) anti-Langmuir isotherm. (Reproduced with permission from P.A. Sewell, D. Kelly, *Chromatographic Separations*, 1987,[90] Copyright, John Wiley & Sons Ltd, 1987.)

Figure 23 Functional overview of refractive index detector. (Reproduced with permission from E.D. Katz, *High Performance Chromatography: Principles and Methods in Biotechnology*, 1996,[91] Copyright, John Wiley & Sons Ltd, 1996.)

transfer resistance. As previously stated, in RPC broad peaks can also indicate that part of the protein sample has undergone a conformational change. As shown in Figure 22(a) Gaussian-shaped peaks are indicative of linear behavior.[90] Here the distribution coefficient for a given component is independent of concentration. Figure 22(b) demonstrates that peaks with sharp fronts and diffuse tails are indicative of Langmuirian behavior. In this scenario the distribution coefficient of a given component decreases when the mobile phase concentration of that component is increased. These peak shapes are typically seen in overloaded preparative applications. Figure 22(c) shows that peaks with diffuse fronts and sharp backs are indicative of anti-Langmuirian behavior. Here the distribution coefficient will increase when the component concentration in the mobile phase is increased. In general detectors are divided into two categories: bulk property detectors and solute property detectors.[91] A thorough review of these detectors is covered by Katz[91] and highlights are presented in this section.

The bulk property detectors sense bulk property changes in the mobile phase solution that contains the solute. These data are compared to a reference that contains pure mobile phase solution. An example of this type of detector is the refractive index detector. This type of detector essentially measures the refraction of light that is passed through a cell containing the solute and the mobile phase. A schematic of this detector is shown in Figure 23. Light is passed through a lens and then through the sample cells. The photocell sensor measures the refraction of light in both cells and records the difference. This value is linearized and then amplified for the output. Refractive index detectors are widely used, inexpensive and simple. The sensitivity of this detector is of the order of $1 \times 10^{-6}\,\mathrm{g\,mL^{-1}}$. They are, however, highly sensitive to temperature and pressure changes. Also the use of a reference cell prohibits the use of gradients. These restrictions severely limit the use of this type of detector in protein purification methods.

Another type of bulk detector is the electrical conductivity detector. This detector is both sensitive and linear; however, it is limited to detecting the presence of ionic materials such as organic acids, bases, salts, amino acids and peptides. The detector cell has two electrodes that are energized with an AC voltage ranging from 1 to 10 kHz. When ionic analytes pass through the cell the impedance of the system changes. This change in impedance is then linearized to produce an output that is linearly related to the solute concentration. The sensitivity of this detector is of the order of $5 \times 10^{-9}\,\mathrm{g\,mL^{-1}}$.

The second category of detector is the solute property detectors. These detectors sense some chemical or physical property change in the solute. An example of this is the UV (ultraviolet) detector. These detectors pass UV light through the sample cell. The solute absorbs a portion of the light and the remainder of light passes through the cell into a photocell where the signal is measured,

linearized and sent to the output. There are three types of UV detector. The first type is a fixed wavelength detector (Figure 24a). The light source in these detectors emits light at fixed wavelengths. These types of detectors have only limited use in analytical applications because of the presence of a reference cell. As with the refractive index detector, the presence of a reference cell eliminates the use of gradients as a means of eluting products from the column.

The variable wavelength detector is the second type of UV detector (Figure 24b). The light source in these detectors is a deuterium lamp. Deuterium lamps are broad band UV sources that emit UV light at a number of different wavelengths. Light is deflected from two concave mirrors onto a grating. The light is then reflected from the grating onto two concave mirrors in series and then through a plane mirror followed by a lens. The light continues through the flow cell where a portion is absorbed and the remaining unabsorbed light is measured by a photocell. The operating principle is similar to the fixed wavelength detector with two exceptions. First, there is no reference cell, and second the wavelength of the light-emitting source can be changed by rotating the grating. Only one wavelength is passed through the sample, however the ability to select wavelengths allows users to make adjustments for the detection of different products during different runs. Note the major limitation of this detector is that it can only detect sample components that absorb at the wavelength it is configured for. Sample components that absorb light at a wavelength different from the one selected will not be detected.

A third type of UV detector is the diode array detector (Figure 24c). The main difference between this detector and the variable wavelength detector is that multiple wavelengths are passed through the sample and the absorption of multiple wavelengths can be measured simultaneously by the photodiode array. If the sample matrix contains components that absorb light at different wavelengths, detection of each component is possible with a photodiode array. The sensitivity of this detector is of the order of $5 \times 10^{-8}\,\mathrm{g\,mL^{-1}}$.

Another type of solute property detector is the fluorescence detector. Fluorescence detectors are extremely sensitive instruments. They can detect solutes at dilute concentrations of the order of $10^{-9}\,\mathrm{g\,mL^{-1}}$. A diagram of a fluorescence detector is shown in Figure 25. Light from a deuterium source is passed through a series of mirrors and ultimately through the sample. A portion of the light is deflected 90° through the sample cell wall containing rhodamine which acts as a fluorescence substance. The fluorescent light is detected by a photocell. Only one wavelength can be detected. This type of detector is primarily suited to analytical applications where trace analysis is routinely performed. Since samples are rarely fluorescent, they must be derivatized with a fluorescing agent. The higher cost of fluorescence detectors plus

Table 8 Key parameters used for detector specification

Parameter	Definition
Dynamic range	The concentration range over which a detector will provide a response
Response index or linearity	An empirical factor with a nominal range of 0.98–1.02
Linear dynamic range	The concentration range in which the response index remains between 0.98 and 1.02
Detector response	Detector voltage output per unit change in solute concentration
Detector noise level	Any perturbation on the detector output that is not related to an eluted solute
Detector sensitivity	Minimum solute concentration that provides a signal equivalent to twice the noise level
Total system dispersion	Variance contribution to a peak from the various components of the detector
Pressure sensitivity	Change in detector output per unit change in operating pressure
Flow sensitivity	Change in detector output per unit change in flow rate
Operating temperature range and temperature sensitivity	Acceptable temperature range of surroundings Detector output change per unit temperature change

the additional complications associated with derivatization severely limit the use of these types of detector in preparative protein purification applications. They are, however, used in analytical applications for the analysis of analytes at low concentration or analytes that do not possess a UV chromaphore.

The selection of a detector is as important as the selection of the stationary phase and the mobile phase composition. There are many factors to consider when purchasing a detector.[91] A list of key factors is presented in Table 8 along with a brief description. Other types of detectors such as mass spectroscopy and light scattering are also used in analytical experiments. A review of these types of detectors can be found in Rabel and Stobaugh[88] and Dolink.[89]

5 SCALE-UP

The goal of preparative chromatography is to isolate the desired protein at a purity level that is appropriate for dosing. The objective of scale-up is to reproduce the resolution, analysis time and yield achieved in an analytical scale system. Each of these objectives is influenced by certain parameters in the chromatographic process and therefore a discussion of each is presented in this section.

As previously stated, the resolution is defined by Equation (16). This equation shows the resolution to be a function of the number of theoretical plates, the retention time and the selectivity of the desired component. As seen in Equation (17) the number of theoretical plates is a function of the column length. These equations plainly show that the resolution will increase when the column length is increased. This phenomenon is presented in Figure 26. Since the goal of preparative applications is purification, a longer column appears to be more desirable. Although the longer column in this example produces superior results it is important to note that the analysis time also increases. In analytical applications this may be acceptable because the goal of many analytical separations is to gain knowledge about the composition. On the other hand in preparative applications the analysis time directly affects the operating cost, which in turn affects the product cost. Since the preparative biopharmaceutical market is highly competitive, it is critical that the stationary phase, flow rate, column length, column width and particle size be specified with the underlying goal of producing acceptable resolution while maintaining product throughput.

Particle size and porosity are also important parameters. Smaller porous particles are advantageous because the sample is exposed to more active surface area. Additionally, the diffusion distance is shorter in smaller particles. The enhanced surface area coupled with a shorter diffusion path lays the foundation for a more efficient separation. High efficiency provides the framework

Figure 26 Effect of column length on resolution. This figure shows the comparison of the performance of 5-μm columns of 5, 10 and 15-cm lengths. (a) 5-cm column length, (b) 10-cm column length, (c) 15-cm column length. The data from each run were collected at the same flow rate. (Reproduced by permission of Wiley-VCH, a subsidiary of John Wiley & Sons, Inc., from Uwe D. Neue, *HPLC Columns*, 1997,[9] Copyright Wiley-VCH, 1997.)

Figure 27 Effect of particle size on resolution. Comparison of the performance of columns of constant length but variable particle size. ———, 3 μm × 15 cm; - - - - -, 5 μm × 15 cm; — · — · —, 10 μm × 15 cm. (Reproduced by permission of Wiley-VCH, a subsidiary of John Wiley & Sons, Inc., from Uwe D. Neue, *HPLC Columns*, 1997,[9] Copyright Wiley-VCH, 1997.)

for acceptable resolution. An example of this is presented in Figure 27.[9] Particle type (IEC, RPC, HIC, etc.) and particle size have the largest influence on yield and resolution. There is however a trade-off with smaller particles. As the particle size decreases the pressure drop increases, which results in higher pumping cost. In addition to a higher pressure drop, the friction generated by flow through a tightly packed bed increases the temperature within the column. Increases in temperature alter the equilibrium in such a way that the overall adsorption of the analyte is reduced. Also smaller particles are more expensive.

The combined effect of column length and particle size is shown in Figure 28.[9] Here we see that the maximum resolution is equivalent in all cases. Note that as the column length is increased the maximum occurs at a later time. This figure also shows that the resolution is diminished as the analysis time is increased. This is the result of band spreading within the column, primarily caused by axial diffusion at low flow rates.

The column diameter is another design parameter that must be altered during scale-up to accommodate the increased volume. The effects of column diameter are shown in Figure 29,[9] where increasing the column diameter has a minimal effect on the separation. Because of this it is generally preferred to scale up a system by increasing the column diameter while leaving the length constant. Note that the largest diameter used in this illustration is much smaller than the diameter of generally used preparative columns. It is not uncommon to see preparative columns with diameters of 100 mm. Wider diameter columns can, however, introduce the potential for flow distribution problems. If the sample is not evenly distributed when it enters the column, broad peaks and poor resolution will the result.

In SEC scale-up is achieved by maintaining dynamic similarity,[92] when the analytical column and the preparative column have the same L/D and $DV\rho/\mu$ values, where

Figure 28 Combined effect of particle size and column length on resolution. Comparison of four columns with constant ratio of column length to particle size. The maximum resolution achievable is the same for all columns, but the maximum occurs at different analysis times. With the 1-μm column, the maximum cannot be reached since it is outside the pressure limit assumed for this graph. ———, 10 μm × 30 cm; - - - - -, 5 μm × 30 cm; — · — · —, 3 μm × 9 cm; ———, 1 μm × 30 cm. L is the length, D is the diameter, V is the velocity, ρ is the density and μ is the viscosity. The advantage of dynamic similarity is that the elution profile remains unchanged after scale-up. The dynamic similarity approach may also be applicable to HIC, particularly if the scale-up of an HIC column results in a longer length. This is because a longer residence time in the column could lead to conformational changes in the protein structure. If the preparative column and the analytical column are kept dynamically similar (i.e. identical residence times for the sample), conformational changes can be minimized.

The scale-up process requires a tremendous amount of analytical experimentation. To circumvent this, some researchers have focused on the use of rate models to predict elution profiles. A key requirement of a rate model is that the model must accurately describe the equilibrium. Two prominent models that have been reported in the literature for ion exchange are the NISS model[53] developed by Li and Pinto and the steric mass action (SMA) model[93] developed by Brooks and Cramer. Both of these models attempt to describe protein equilibrium on ion-exchange supports. The advantage of modeling is that the amount of experimentation required for scale-up can be reduced. A number of scenarios can be simulated to determine the optimum process parameters. In principle, once these parameters have been obtained, the number of scale-up experiments can be limited to verifying the computer generated results.

Mathematical modeling of protein equilibrium is still in its infancy and more work needs to be done. As modeling efforts continue to develop and improve, our fundamental knowledge of protein–adsorbent interactions will also improve. This increased knowledge will be key in developing purification protocols for future biopharmaceutical products.

6 CONCLUSIONS

The arena of biopharmaceutical proteins and peptides has grown into a billion-dollar-a-year business. This market is expected to grow at a faster pace in the next decade, and with growth will come the need to perform thorough and rapid purifications.

Chromatography is at the core of all biopharmaceutical separations. An overview of the more commonly used chromatographic techniques has been presented. From this overview it was shown that RPC is primarily used for the separation of polypeptides and small proteins that are not very hydrophobic. Protein purification is limited in RPC because of the possibility of denaturation. Proteins are large three-dimensional macromolecules that have a number of hydrophobic patches within their structure. If the stationary phase is strongly hydrophobic then irreversible adsorption or permanent denaturation can occur. HIC is better suited to protein purification than RPC because the stationary phase is less hydrophobic. The environment in HIC is milder and protein elution can be accomplished with salt gradients that reduce the ionic strength of the buffer. Because of this the use of harsh solvents is usually not needed. IEC is also well suited to protein purification because of the amphophilic nature of proteins. Proteins are electrolytic molecules that possess a net charge when the mobile phase pH is either above or below the pI of the protein. IEC exploits small differences in protein net charge to purify mixtures of proteins. AC is used to concentrate valuable proteins that are initially very dilute in solution. The stationary phase in AC elicits specific responses from an analyte. The binding of an analyte with an affinity stationary phase can be thought of in an analogous fashion as a ''hand in a glove'' or a ''key in a lock''. This technique can concentrate the desired analyte over 1000-fold. The stationary phase in AC can be more difficult to synthesize and thus more expensive. SEC is a very popular technique in protein purification. SEC separates proteins by size and/or shape and is frequently used for desalting.

Protein detection can be achieved by a number of methods. The most popular detector is the UV spectrometer. Fluorescence, refractive index, conductivity and light scattering are also used but to a lesser extent in preparative

applications. These techniques are more common in a laboratory setting.

Scale-up of chromatographic columns is usually achieved by increasing the column diameter to allow for a higher throughput. The dynamic similarity approach is used in the scale-up of SEC columns. This technique minimizes the analysis time and maintains the peak order and elution times of each product.

As previously stated, the demand for rapid and thorough protein purification will increase as the biopharmaceutical market continues to grow. To meet this need it is imperative that our knowledge of protein adsorption must also grow. It is vital to focus on research that improves our fundamental understanding of the mechanisms governing protein adsorption. As our knowledge in this phenomenon improves, it will be possible to refine existing techniques and create new protocols to meet better the needs of the ever growing biopharmaceutical market.

ABBREVIATIONS AND ACRONYMS

AC	Affinity Chromatography
ADA	Adenosine Deaminase
AIDS	Acquired Immunodeficiency Syndrome
ASP	Aspartyl
FDA	Food and Drug Administration
GFC	Gel Filtration Chromatography

Quantitative structure–activity relationships (QSARs) are mathematical equations or other types of functions (such as the weights of connections in artificial neural networks) relating chemical structures to their biological activity. The purpose of QSAR studies is to predict novel structures with either beneficial activity as drugs for human or veterinary medicine (bactericides, antiviral or anticancer drugs, and metabolic regulators, such as hypoglycemics, hypotensives, etc.), or selective toxicity for various unwanted higher organisms (pesticides such as fungicides, insecticides, acaricides, weed killers, etc.) Quantitative structure–property relationships (QSPRs) are similar, but the property may be physical or chemical. The main problems involve

1. *finding a mathematical representation of chemical structures (usually organic molecules), represented either as molecular graphs by their constitution or connectivity without considering the three-dimensional (3-D) (stereochemical) factors, or as 3-D objects including stereochemical information;*
2. *measuring the biological activities of a series of molecules;*
3. *finding the QSAR between each type of biological activity and the most convenient molecular descriptors.*

Physicochemical parameters that are closely related to drug transport and ligand binding include lipophilicity, polarity, polarizability, and electronic influence on hydrogen-donor and hydrogen-acceptor binding. The next task is to use the QSAR to predict which novel structures to prepare in order to obtain molecules with the desired biological activity. Then the cycle is usually repeated, because a single pass seldom affords the optimal solution.

The main mathematical descriptors and the techniques for obtaining QSARs are reviewed. An important molecular parameter, which may be measured experimentally or computed from the chemical structure, is lipophilicity or hydrophobicity; Hansch introduced the n-octanol–water partition coefficient as a measure of this property, which, to a large extent, determines the ability of molecules to penetrate the lipophilic, bilayer, extra- or intracellular membranes. Lipophilicity levels that are too high lead to insolubility in water, i.e. it is difficult to administer the drug orally via the digestive tract. The main constitutional and 3-D molecular descriptors are described and examples are given. To be statistically valid, correlations must involve orthogonal or orthogonalized descriptors. Linear, multilinear, and nonlinear types of correlations are reviewed. Screening of virtual combinatorial libraries together with high-throughput combinatorial synthesis and testing provides modern tools for more efficient drug design.

1 INTRODUCTION

A fitting introduction for the importance of analytical chemistry for QSAR in drug design[1] is provided in the following quotation, reproduced with permission[2]:

> Over the last two decades the art of drug discovery has changed dramatically with the introduction of new analytical tools. Analytical chemistry revolutionized both the analysis of chemical compounds and the study of biological processes. Today crystallography and NMR (nuclear magnetic resonance) contribute significantly to biostructural research and have led to the unraveling of many details about the structure and functions of macromolecules, such as nucleic acids and proteins. The second revolution, developed in parallel and which is now indispensable, concerns the use of computers in molecular design and in the lead discovery process.

These phrases, written in 1994 by van de Waterbeemd,[2] must now be supplemented by the contribution brought about by high-throughput analytical techniques, which detect biological activity in minute amounts of substances synthesized simultaneously in combinatorial libraries numbering thousands of compounds. Only a very small number of these substances are then prepared in sufficient amounts for chemical and biological characterization and testing, namely, those that show a positive response to fluorescent, radiochemical, immunochemical, or other analytical techniques. Thus, although the total number of substances registered by *Chemical Abstracts* is now about 30 million, with an average yearly increase of 0.6–1.0 million, this number will not jump spectacularly with the advent of combinatorial libraries, because only characterized compounds are registered.

It is estimated that before the advent of combinatorial chemistry, for each drug that reached the market, about 5000 compounds had to be synthesized and tested over about 15 years, and thus the cost was US $\$10^{10}$–$10^{11}$. It is hoped that both the cost and the duration of new drug launches will be decreased by combinatorial libraries (virtual and experimental) and high-throughput screening, and that QSARs will help to reduce the number of substances that have to be tested.

The vast majorities of novel compounds characterized each year are organic substances with presumed beneficial biological activity, and are synthesized by the major drug companies and by research universities. The necessity of continuously looking for new medicinal drugs originates in a multitude of factors, among which the most important are as follows:

1. the fact that pathogens develop resistance (nowadays few of the ''wonder antibiotics'' of the 1950s are still useful);
2. the discovery of genetically derived metabolic disorders (the Human Genome Project having completed its task, the complete mapping of the human genome) provides clues for curing such disorders, mainly through computer-aided design of small molecules that can act as receptor blockers or activators for crucial proteins;
3. the need for improving the efficiency of existing drugs learning from the experience of the past, and giving rise to new generations of drugs;
4. developments in the knowledge of biochemical pathways and of the interconnection between the complex networks involved, as well as the opening of new areas such as the mechanisms of memory, neurology disorders, and various forms of cancer.

The huge costs associated with drug discovery, including in vitro and in vivo tests (the latter finalized in lengthy clinical trials), have to be recovered by the drug manufacturing companies during a relatively short time interval under the present patent laws. Insurance companies prefer generic drugs that are less expensive after the patent expires, but very few manufacturers of generic drugs contribute to the research effort.

Computational techniques have now made possible a third type of screening, in addition to the in vitro and in vivo tests, often called *in silico tests*. Virtual combinatorial libraries, including far larger numbers of structures than can presently be explored experimentally even by the most high-performance combinatorial approaches, can be screened by computers, provided that a sufficient number of reliable experimental data exist to obtain meaningful QSAR studies. An eloquent example is provided by a recent report published by Grassy et al.[3] The activity of the lead immunosuppressive peptide for skin and heart allograft survival in mice was increased about 100 times by a computer-assisted design using 13 molecular descriptors. With 35 natural and nonnatural amino acids that could occupy the seven positions of the relevant portion of the peptidic chain, the virtual combinatorial library would have numbered $35^7 \cong 64$ billion structures. A first filter based on the lipophilicity reduced the number of amino acids to six (one nonnatural and five natural amino acids). All the resulting $6^7 \cong 280\,000$ structures were calculated to ascertain whether their 13 descriptors fitted into the favorable domains previously determined from the learning set of about 20 active and inactive compounds. These descriptors, independent of 3-D factors and therefore very fast to compute, are discussed later. Only 26 peptides passed this test, i.e. one in about 10 000, and they were analyzed by molecular dynamics simulations to compare the similarity between their conformational space and that of the active peptides.

The five peptides that passed this last filter were synthesized and tested in vivo; one of these was about 100 times more active than the best peptide known until then.

Among the molecular descriptors, this review describes topological indices (TIs) in more detail than is usually encountered in the overviews of QSARs. The reasons for doing this are that

1. such molecular descriptors deserve to be better known because they have a bright future for screening of virtual libraries;
2. chemometric methods may also profit from this approach;
3. TIs have been intensively developed for QSARs and QSPR purposes by the author.

2 CLASSICAL AND PRESENT DAY QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIP PARADIGMS

From the rich literature on QSARs, several post-1978 references have been selected.[4–73] The literature on QSPRs is almost as rich, and again only a few leading references have been provided.[66,74–80] The classical approach to drug design involved the following steps[5]:

1. A known active structure (the lead compound) may be discovered by chance in random screening, by testing many natural products, or in the search for another type of bioactivity (as examples, the erectile activity of Viagra-like compounds was discovered in clinical trials during the search for a hypotensive drug, and oral antidiabetics such as tolbutamide were developed after observing the hypoglycemic activity of new sulfa drugs). Alternatively, enzyme inhibitors may be designed by analogy with enzyme substrates, by the receptor-mapping method, or by Lindquist's transition state analogs.
2. An exploratory series patterned after the lead compound is generated either by combinatorial chemistry (the preferred contemporary method, when a high-throughput screening is available and when the number of congeneric structures is considerable) or by normal stepwise syntheses. At this stage, rational design methods can come into play, as is shown further (Free–Wilson method, extra thermodynamic approach, etc.).
3. On the basis of the bioactivity results of this test series, it is possible to formulate a QSAR using various approaches (molecular descriptors and computer programs, i.e. software) at different levels of sophistication.
4. Finally, on the basis of the QSAR study, it should be possible to predict structures that optimize the beneficial activity of the lead compound, and at the same time minimize the unwanted side effects, most importantly the toxicity.

The ratio between the beneficial and toxic doses is called *the therapeutic ratio*, and drug designers strive to arrive at structures with optimal therapeutic ratios. (Other unwanted side effects are also important, as shown by the example of thalidomide, which had passed clinical trials and was put on the market in Europe for one year, because at that time no test had discovered that one of its two stereoisomers had severe teratogenic effects.)

Present day paradigms may change the weight and the order of experimental versus computational approaches. The facility of virtual library screening when there is enough experimental material with established bioactivity data enhances the weight of the computer-assisted drug design (CADD) phase. Actually, neither this acronym nor computer-aided molecular design (CAMD) are the best descriptors, and should be replaced by computer-aided ligand design (CALD), as argued by Boyd.[67] CALD is more accurate because computers are not used to design drugs directly, but instead are used to design small molecules (ligands) that may bind specifically to a larger biomolecule, and thus may have a beneficial effect; however, many such ligands have to be tested until a drug is obtained. Combinatorial chemistry techniques also greatly increase the potential for experimental exploration of congeners having the same molecular skeleton (scaffold) and differing in their substitution patterns. In both cases, however, one has to have a lead compound and a test series for an initial QSAR. As a result, one can either explore huge virtual combinatorial libraries and experimentally test only a few compounds,[3] or one can rely on the power of combinatorial synthesis and high-throughput testing to experimentally explore thousands of compounds, and then develop a powerful and very reliable QSAR. In both approaches, several such cycles may be necessary.

Many QSAR data on biological activities have not been obtained with whole organisms or living cell cultures, but with purified enzymes. Often their molecular structure has been determined by X-ray diffractometry in the crystal, or more recently by NMR in solution (with geometry closer to that which is responsible for the catalytic activity of the enzyme). In some cases, the mechanism of this catalytic activity is known in detail. The accuracy and reproducibility of QSAR data for enzyme inhibition are much higher than those of in vivo studies.

3 CHEMICAL STRUCTURE: CONSTITUTIONAL AND STERIC ISOMERISM

3.1 Atomic Bonds

Covalent bonds are the strongest chemical bonds and they hold atoms together in molecules that are unchanged in all three states of matter (crystalline, liquid, and gaseous). Neither phase transitions nor solvation has any effect on such bonds. Ionic and metallic bonds are usually weaker; the former are compensated for in aqueous solutions by ion – dipole interactions so that ions move independently. For ionic or metallic solids, only empirical formulae (e.g., NaCl, $CaCl_2$), which provide information on the relative numbers of atoms, are meaningful. However, for compounds with covalent bonds, molecular formulae are more meaningful than empirical formulae, because they also provide information on the absolute number of atoms in the molecule. Thus, acetylene and benzene both have the same empirical formula, CH, but their molecular formulae are different: C_2H_2 and C_6H_6, respectively.

3.2 Molecular Bonds

Intermolecular forces (hydrogen bonds, dipole interactions, dispersion or London forces, hydrophobic interactions) are not chemical bonds, i.e. do not lead to stable chemical compounds, but are responsible for the existence of condensed phases (liquid and crystalline), and play an important role in biochemical processes. These forces are much weaker than chemical bonds, and hence they lead to associations that are reversible and depend strongly on the surroundings, as is necessary in enzymatic reactions. The van der Waals' intermolecular interactions are both weakly attractive at larger distances r and highly repulsive at lower distances. The simplest expression for van der Waals' interaction energies is the Lennard–Jones potential energy: $E_{vdW} = (a/r^{12}) - (b/r^6)$, with constants a and b to be determined.

3.3 Isomers

Most of the chemical bonds in organic compounds are covalent bonds. Isomers are different compounds that share the same molecular formula. There is just one stable compound, acetylene, with the molecular formula C_2H_2; however, acetylene, which has a triple bond between two CH groups, may rearrange to vinylidene, $M{=}C{=}CH_2$, when adsorbed on a metallic catalyst (M). There are many structures isomeric with benzene, but only one of these has a planar regular hexagonal structure with six CH groups and ''delocalized'' or ''aromatic'' C–C bonds. Four of these isomers are called *valence isomers* because like benzene they have six CH groups, but the bonding is different.[81]

It is customary to classify isomers into *constitutional* and *steric* isomers. Constitutional isomers differ in their connectivity patterns, e.g. *n*-butane and isobutane (which have the common molecular formula C_4H_{10}) have a linear and a branched chain, respectively, of four carbon atoms with single bonds between them. Their constitutional formulae may be written in Smiles notation,[32] which neglects single bonds, as CCCC and CC(C)C, respectively (when also neglecting the hydrogen atoms, as is usual in molecular graphs for hydrocarbons). Other examples of constitutional isomers are ethanol and dimethyl ether (C_2H_6O), which have the hydrogen-depleted constitutional formulae CCO and COC, respectively; 1-fluoropropane and 2-fluoropropane (C_3H_7F), with constitutional formulae FCCC and CC(F)C, respectively; and 1-butene and 2-butene (C_4H_8) with constitutional formulae C=CCC and CC=CC, respectively. All such constitutional isomers may be represented mathematically by molecular graphs, where vertices (points) symbolize atoms, and edges (lines) correspond to covalent bonds. In other types of graphs used in chemistry, such as reaction graphs, vertices symbolize chemical species and edges represent elementary reaction steps.

Stereoisomers have the same constitutional formulae, but differ in the geometrical 3-D disposition of bonds. Steric isomers are of two kinds:

- *diastereoisomers* or *diastereomers*, whose properties differ as much as those of constitutional isomers; they are characterized either by differences in distances between nonbonded atoms (e.g. cis/trans or Z/E isomers of polysubstituted compounds with rings such as 1,2-disubstituted cycloalkanes or with double bonds such as 2-butene) or by the presence of several chiral centers and an absence of mirror-image symmetry;
- *enantiomers*, which are nonsuperimposable mirror images of one another, and whose properties are identical except for those involving interaction with chiral forms of energy (such as plane-polarized photons) or matter (such as chiral solvents and biomolecules or bioreceptors).

Natural compounds synthesized enzymatically by living cells are produced as single enantiomers, whereas chemical reactions carried out in the absence of chiral catalysts yield mixtures of enantiomers (mixtures of equal amounts of two enantiomers with opposite chirality are called *racemic mixtures*, after the historical discovery by Louis Pasteur in the case of tartaric acids). A tetrahedral carbon atom with sp^3 hybridization and with four different substituents can have two nonsuperimposable (chiral) configurations leading to

a pair of enantiomers; a pentacovalent atom with trigonal – bipyramidal geometry gives rise to 10 pairs of enantiomers when it has five different substituents; a hexacovalent atom with octahedral geometry affords 15 pairs of enantiomers when all its six substituents are different.

In addition to these types of isomerism, which are seen at normal temperatures because of differences in molecular properties and the possibility of separating isomers, there is also the possibility of conformational isomerism, which does not usually result in isolatable compounds at normal temperatures because of low energy barriers toward rotation around single bonds. However, at lower temperatures, or when rotation barriers are high owing to electronic or steric factors, ''rotamers'' may become stable enough to be separated.

4 CHEMICAL CODING OF STRUCTURES

For a long time, the Chemical Abstracts Service (CAS) used an extended Morgan algorithm for coding molecular constitutions (connectivity), and more recently a 3-D coding algorithm, CONCORD, has been used. So far, however, parts of the 3-D structures have not been correct in their absolute configuration. The CAS registry number is uniquely associated with a substance or an industrially produced mixture of substances, but bears no relationship to the chemical structure. Linear notation systems (e.g. the Wiswesser line notation) rely on elaborate conventions and are outmoded.

By contrast, the algorithmic structure display of CAS[82] is able to convert a chemical graph into a connection table and vice versa, allowing rapid structure or substructure searches of all known compounds. This fact makes chemistry the best documented science because it does not rely on words and semantics for accessing information on any chemical structure or substructure. Independent of their own language, chemists can communicate the constitution of chemical compounds via graphs. However, when words are needed, as when searching for properties or phenomena, documentation in chemistry is no longer any better than in other sciences such as mathematics, physics, biology, or medicine.

For molecules with N nonhydrogen atoms represented as constitutional (molecular) hydrogen-depleted graphs, chemical constitution is easily encoded as an adjacency matrix **A**, whose entries a_{ij} are 1 for two adjacent atoms i and j (i.e. atoms which are connected by a covalent bond) and 0 otherwise. The result is a symmetrical matrix with N rows and columns. The sum v_i over row or column i is called the *degree of vertex i*; for instance, a quaternary carbon atom (connected to four other C atoms) has degree $v_i = 4$, and a secondary carbon atom has degree $v_i = 2$.

More detailed topological information is provided by the distance matrix **D**, whose entries d_{ij} represent topological distances between vertices i and j, i.e. the number of bonds along the shortest path between these vertices. Thus, both matrices **A** and **D** have zeros along the main diagonal and the same entries 1, but all off-diagonal zeros in **A** are replaced in **D** by integers that are larger than 1. Sums of entries along row or column i in **D** are called *distance sums* (distasums) d_i.

Both matrices **A** and **D** contain all the necessary information to calculate the molecular constitution. TIs have been devised using these matrices as a basis. It had been conjectured that the eigenvalues (EVAs) or characteristic polynomials of **A** or **D** could uniquely characterize a chemical graph, but this conjecture was proved to be unfounded.[83]

5 HYDROPHOBICITY OR LIPOPHILICITY PARAMETERS

Historically, the QSAR has its origins in the first attempts (Crum-Brown and Frazer, 1868) to quantitatively connect the biological effects of alkaloids with their chemical structure. In 1893, Richet discovered an inverse relationship between differences in the toxicity of organic compounds and their water solubility. Meyer (1899) and Overton (1901) expressed a correlation between narcotic activity and lipophilicity using oil–water partition coefficients, forerunners of log P values. Fühner and Neubauer (1906) showed that narcotic activities increase regularly in homologous series, suggesting the additivity of group contributions, a theory which was developed further by Bruice, Kharasch, and Winzler in 1956. Ferguson's principle, formulated in 1939 at the ICI laboratories, linked the narcotic activity with thermodynamic equilibria governed by the partition coefficient, creating the basis for the development of halothane anesthetics. Further investigations by Albert, initiated in the 1940s, linked the antiseptic activity of acridine derivatives with their ionization equilibria. Zahradnik and Hansen are also considered to be pioneers in this area because in 1960–1962 they applied Hammett's approach to biological data. Details of references for these early efforts may be found in some of the cited monographs.[5,31–39,49]

The official birthdate for the QSAR is considered to be 1962, when Hansch et al.[84] made the connection between biological activities (expressed logarithmically in terms of the molar concentration C of compounds producing a standard response in a constant time interval) and the octanol–water partition coefficient P for a substituted

derivative $X–R$ of the parent aromatic compound H–R, expressed by analogy with Hammett's parameters as Equation (1).

$$\log\left(\frac{P_{X-R}}{P_{H-R}}\right) = \pi_X \tag{1}$$

Hansch et al.[85,86] then combined two parameters for explaining biological activities, one parameter being the Hammett substituent constant σ, and the other the lipophilicity, π or log P, as shown in Equation (2).

$$\log\left(\frac{1}{C}\right) = k_1\pi + k_2\sigma + k_3 \tag{2}$$

On the basis of the observation that there is often an optimal lipophilicity, a parabolic equation in terms of log P or π (Equation 3) was introduced by Hansch and Clayton in the early 1960s and reviewed in 1969.[87,88] They also combined lipophilicity not only with an electronic parameter (Hammett's σ) but also with a steric parameter (Taft's E_s constant, Equation 4), and devised nonlinear relationships in terms of log P (Equations 5 and 6):

$$\log\left(\frac{1}{C}\right) = k_1\pi - k_2\pi^2 + k_3\sigma + k_4 \tag{3}$$

$$\log\left(\frac{1}{C}\right) = k_1\pi + k_2E_s + k_3\sigma + k_4 \tag{4}$$

$$\log\left(\frac{1}{C}\right) = k_1\log P - k_2\log(k_3P + 1) + k_4\sigma + \cdots + k_5 \tag{5}$$

$$\log\left(\frac{1}{C}\right) = k_1\pi - k_2\log(k_3 10^{\pi} + 1) + k_4\sigma + \cdots + k_5 \tag{6}$$

Equations (2)–(6) are all extrathermodynamic.[5,37] The choice of *n*-octanol proved to be an ideal one because, being similar to biological membranes (a polar head plus a nonpolar tail), it dissolves most druglike substances (unlike alkanes, lower alcohols, or water). In addition, although it is practically insoluble in water, octanol dissolves enough in water (2.3 M) for solutes to pass into the organic phase with their hydration shell so that they do not associate with each other. Also, octanol has a low volatility and does not absorb in the ultraviolet (UV) region. Differences between partition coefficients for aqueous solutes using *n*-hexane and octanol as organic solvents may serve as quantitative measures for the hydration/dehydration properties of molecules or substituents. Such hydrophobic interactions are responsible for micelle formation and are important for biomolecules such as proteins, or for receptor–agonist (pharmacophore) interactions.

Partition coefficients (log P) may be obtained experimentally either by the "shake flask" method, or more conveniently by high-performance liquid chromatography (HPLC) measurements on reversed-phase HPLC columns and subsequent adjustment of the retention times with correction factors using standard substances.[89] However, theoretical algorithms for computing log P values for any known or unknown molecule are available nowadays. Starting with Hopfinger and continuing with Reynolds, Klopman, Bodor, Reddy, Katagi, and their coworkers, various quantum-chemical methods were devised.[5,31–39,49] The algorithms most often used at present are those using either

1. a fragmental approach initiated by Rekker et al.[90–94] who recognized that to be able to include araliphatic and aliphatic compounds, a different method had to be employed see also[95];
2. atomic contributions, which form the basis of a computational method proposed by Ghose and Crippen (110 types of covalently bonded atom types).[96]

Rekker's idea was later developed further.[19,97–101] Chou and Jurs launched a computer program called *CLOGP*[102,103]; other programs are also available.[104]

6 DESCRIPTORS FOR ELECTRONIC, POLAR, AND STERIC FACTORS

In 1937, Hammett took the initiative in expressing quantitatively the electron-donating or electron-withdrawing effect of substituents X.[103,105,106] He investigated meta- or para-X-substituted benzyl derivatives, and found that rates of reactions involving the bond-breaking of the benzyl group (k_X) were correlated with ionization constants $K_{a,X}$ of the benzoic acids with the same substitution pattern. Electronic effects can be expressed by the substituent constants σ_{meta} or σ_{para} defined as in Equation (7).

$$\sigma_X = \log K_{a,H}(\text{benzoic acid}) - \log K_{a,X}(\text{X} = \text{substituted benzoic acid}) \tag{7}$$

The rate correlation can be expressed by Equation (8):

$$\log\left(\frac{k_X}{k_H}\right) = \rho\sigma_X \tag{8}$$

where ρ denotes the sensitivity of the reaction to electronic effects.[33,102,103] Since Equation (8) relates

thermodynamic to kinetic data (activation energies), it is a linear free-energy relationship (LFER) like the Brønsted relationship. Many physical properties of substituted benzene derivatives can also be correlated with Hammett's σ parameters.

In addition to electronic effects transmitted through space or via bonds, polar interactions result either from polarization or polarizability of molecules. *Polarization* is a permanent effect due to electrical charges or dipole moments. As an example, the greatest difference in normal boiling points for two homologous molecules differing only by one methylene (CH_2 group) is observed for oxalonitrile (cyanogen), which boils at $-22\,^{\circ}C$, and malononitrile, which boils at $219\,^{\circ}C$ under normal pressure; the explanation lies in the fact that the former dinitrile is linear and symmetric and has no dipole moment, whereas the latter dinitrile is V-shaped and has a high dipole moment (3.58 D).[107] *Polarizability* is due to the dynamic response of electrons in molecules and gives rise to dispersion forces. These forces can best be described by molar refractivities (MRs), which have an electronic component proportional to the polarizability, and are obtained as shown in Equation (9) from the refractive indices n and the molar volumes V (hence they are also related to steric parameters).

$$MR = \frac{V(n^2 - 1)}{n^2 + 2} \tag{9}$$

ortho-Substituted benzoic acids and benzylic derivatives do not behave normally in Hammett-type correlations because of steric effects. Taft, therefore, later introduced his steric parameter E_s.[108] Subsequent developments included the separation of inductive effects from resonance effects, the extension of the Hammett equation to polycyclic, polysubstituted, or heterocyclic aromatics, the definition of various scales for electrically charged substituents or reagents, and the use of nonaromatic scaffolds linking the substituent with the reaction center (such as four-substituted bicyclo[2.2.2]octane-carboxylic acids).[109,110]

Other steric parameters have been introduced by Charton[110] and by Verloop et al.[111] Verloop et al. introduced five parameters for substituents, called *STERIMOL*; the first (L) indicates the length of the substituent in the direction of its attachment to the molecular scaffold; the remaining four ($B_1 - B_4$) are dimensions along four directions perpendicular to the first, so that substituent flexibility can also be taken into account. The ratios L/B_1 and B_4/B_1 (the latter being the ratio of maximum to minimum width) measure the dimensions of the substituent when approximated as an ellipsoid. Usually, QSAR equations employing the STERIMOL method involve only these last three parameters. All previously mentioned steric parameters, together or separately, may enter QSAR equations in linear or quadratic polynomials.

Beginning in 1973, Simon and others introduced the concept of *minimal topological difference* (*MTD*) (an earlier version was called *minimal steric difference* (*MSD*)).[6–8] The postulates of this approach are as follows:

1. the binding site of the biological receptor is assumed to be a cavity into which the agonist (drug or ligand molecule), in its graph-theoretical representation neglecting hydrogen atoms fits relatively tightly;
2. atoms or groups of atoms within the cavity are favored sterically, and contribute by lowering the potential energy ($\varepsilon_j = -1$);
3. atoms or groups of atoms interfering with the cavity wall inhibit binding sterically, and increase the total energy ($\varepsilon_j = +1$);
4. atoms or groups of atoms left outside the cavity are of no steric significance, and have no contribution to binding ($\varepsilon_j = 0$).

Mapping several bioactive molecules over one another in their most favorable topology or geometry gives rise to an imaginary hypermolecule. From overlapping vertices with each nonhydrogen atom j of the hypermolecule and agonist i (x_{ij} is 1 when overlapping and 0 otherwise) one can reckon the MTD_i for molecule i as shown in Equation (10) (S is the number of cavity vertices having $\varepsilon_j = -1$ in the hypermolecule):

$$MTD_i = -S + \sum_j \varepsilon_j x_{ij} \tag{10}$$

Simon's approach was the basis for later studies by Hopfinger[112] and Amoore.[113]

7 THE FREE–WILSON (de novo) METHOD

Assuming that biological effects of substituents attached to a molecular scaffold are additive, Free and Wilson[114] started with a series of compounds with the same skeleton, but with various substituents in more than one position, and with each substituent occurring more than once at each position in which it is found. Ban and Fujita reformulated Free and Wilson's method using logarithms of biological activities, and the unsubstituted scaffold as standard.[115] The mathematical background of this QSAR involves indicator variables (0 for the absence and 1 for the presence of a substituent at a particular position) in a matrix, plus the vector of the corresponding potency

values, allowing a multiple regression calculation. This method is subject to the following two restrictions.

1. The minimum number of compounds in the series must be larger than the number $\tilde{N}$ of parameters in the regression equation, i.e. (Equation 11)

$$\tilde{N} = 1 + \sum_j (n_i - 1) \tag{11}$$

   where j is the number of available positions on the scaffold for substitution and n_i is the number of various substituents at position i. Usually, an excess of about five compounds over $\tilde{N}$ yields a minimum number of degrees of freedom for accurate statistical analyses.
2. No two substituents should always be present in combination; if they are, their sum can be considered as a single pseudosubstituent.

An example of antiadrenergic activities of *N*,*N*-dimethyl-α-bromophenethylamines with $j = 2$ positions for para (Y) and/or meta (X) substituents follows.[116,117] The series consisted of 22 compounds, and the $n_i = 5$ substituent positions were occupied by X/Y = H, F, Cl, Br, I, or Me groups. The resulting QSAR equation is shown in Equation (12):

$$\begin{aligned}\log\left(\frac{1}{C}\right) = {} & -0.30(\pm 0.50)[m\text{-F}] + 0.21(\pm 0.29)[m\text{-Cl}] \\ & + 0.43(\pm 0.27)[m\text{-Br}] + 0.58(\pm 0.50)[m\text{-I}] \\ & + 0.45(\pm 0.27)[m\text{-Me}] + 0.34(\pm 0.30)[p\text{-F}] \\ & + 0.77(\pm 0.30)[p\text{-Cl}] + 1.02(\pm 0.30)[p\text{-Br}] \\ & + 1.43(\pm 0.50)[p\text{-I}] + 1.26(\pm 0.33)[p\text{-Me}] \\ & + 7.82(\pm 0.27)\end{aligned} \tag{12}$$

and the statistical data were $n = 22$, $r = 0.969$, $s = 0.194$, $F = 17$.

One shortcoming of the Free–Wilson model is the necessity for series that are large enough to have structural variation in at least two different positions of substitution. A large number of parameters is thus needed to describe relatively few compounds; in the above example, $\tilde{N} = 10$ parameters with 22 compounds leaves only $22 - (10 + 1) = 11$ degrees of freedom. If a substituent occurs only once in the data set, this single-point determination will contribute with its full error to this one biological value. Most significantly, predictions for combinations of substituents that were not present in the series are limited to n_i^j minus the number of degrees of freedom, i.e. $5^2 - 11 = 14$ compounds in this case. No extrapolation to other types of substituents or other substituent positions is allowed.

If the numbers of substituents in positions $a, b, c, \ldots$ are denoted by $n_a, n_b, n_c, \ldots$, the above number of predictions should be replaced by $(n_a + 1)(n_b + 1)(n_c + 1)\cdots - V$, where V is the total number of observed values.

A mixed approach, combining the Free–Wilson and the Hansch methods, solves some of these drawbacks.[118,119] Although log P lipophilicities do not differentiate among stereoisomeric substituents, the Free–Wilson method can take such factors into account. The latter method was also successfully applied to peptide design.[120]

8 TOPOLOGICAL INDICES AND THEIR USES IN QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIPS

The central problem in QSARs is to convert chemical structures into mathematical molecular descriptors that are relevant to the mechanism of the biological activity. Katritzky and Gordeeva.[79] showed that for QSPR studies, TIs are among the best descriptors, but for QSAR studies they have to be complemented with other parameters (such as log P, which is involved in molecular transport across biological membranes).

Recalling what was mentioned in Section 4, one may start from the simplest representation of agonist molecules (potential drugs in CALD) as molecular graphs. Their constitution is encoded in matrix form (adjacency matrix **A**, or distance matrix **D**). Irrespective of the arbitrary labeling of vertices, the sums over row i or column i of these two matrices, v_i and d_i, respectively, are local vertex invariants (LOVIs). The degree v_i of vertex i in organic molecules can be an integer from 1 to 4, but there is no limit for the distasum d_i.

From these or related LOVIs, one can obtain global molecular descriptors, called *TIs*, via mathematical operations such as summation, summation of squares, summation of products over edge endpoints, etc. The simplest *(first-generation)* TIs are integer numbers obtained from these integer LOVIs.[121,122] Thus, one of the first and still useful TIs was proposed by Wiener as the half-sum of distasums, and the result shown in Equation (13), is known as *Wiener's index*[123]:

$$W = \frac{\left(\sum_i d_i\right)}{2} \tag{13}$$

Another first-generation TI is the sum of squares of vertex degrees,[124] shown in Equation (14).

$$M_1 = \sum_i v_i^2 \tag{14}$$

Centric indices for acyclic graphs were obtained by Balaban in 1979 by summing squares of numbers of vertices pruned stepwise from the periphery toward the graph center, which is either one vertex or a pair of adjacent vertices.[125] This idea was later generalized for cyclic graphs,[126] and for substituents.[127]

Second-generation TIs are real numbers based on integer LOVIs. One of the most successful TIs, the molecular connectivity (χ), was proposed by Randic in 1975 as the sum (over all edges $i-j$ in the graph) of the reciprocal square root of products of vertex degrees for edge endpoints (Equation 15), where the LOVIs are vertex degrees v_i and v_j[128]:

$$\chi = \sum_{ij} (v_i v_j)^{-1/2} \tag{15}$$

This idea was then generalized for longer paths than edges (which can be considered as paths of length 1 in the graph). The three carbon atoms in a propane graph form a path of length 2, an *n*-butane graph is a path of length 3, and so on. An isobutane graph is a cluster (star graph) on four vertices. Two Kier–Hall monographs[129,130] presented many successful QSAR data using their extended connectivities; a third book describes their electrotopological state index.[131] All these indices have recently been reviewed.[132–134]

To take into account the nature of atoms symbolized by vertices, Kier and Hall advocated the use of ''valence connectivity indices''.[135] These are calculated using formulae similar to Randic's (Equation 15), but products of edge endpoint (or path–vertex) invariants are no longer vertex degrees but weights (valence delta values δ_i) given by Equation (16):

$$\delta_i = \frac{Z_i^v - H_i}{Z_i - Z_i^v - 1} \tag{16}$$

where Z_i^v stands for the number of valence electrons in atom i, Z_i is its atomic number, and H_i is the number of hydrogen atoms attached to atom i.

Kappa indexes developed by Kier are calculated relative to structures that correspond to the least-branched (linear chain) and most-branched (star graph) molecule with the same number A of nonhydrogen atoms. For paths ${}^L P_i$ of length L (i.e. the count of contiguous two-bond fragments), the result is shown in Equation (17).

$${}^L\kappa = \frac{2\left({}^L P_{\max} \times {}^L P_{\min}\right)}{\left({}^L P_i\right)^2} \tag{17}$$

As mentioned earlier, an edge is a path of length $L = 1$. The nature of atoms is taken into account via a corrective factor α, which is derived from the covalent radius of an atom relative to that of an sp^3-hybridized carbon. For ${}^2\kappa_\alpha$ as shown in Equation (18) we obtain

$${}^2\kappa_\alpha = \frac{(A+\alpha-1)(A+\alpha-2)^2}{({}^2P_i+\alpha)^2} \tag{18}$$

Later, Kier introduced a flexibility index,[21,133,136] defined as $\phi = ({}^1\kappa_\alpha \times {}^2\kappa_\alpha)/A$. For a linear alkane, $\phi = A - 1$, i.e. the count of $C(sp^3)-C(sp^3)$ bonds.

No TI proposed so far is free of degeneracy (more than one structure sharing the same value of the index), and all TIs depend both on molecular branching and molecular size. For some TIs it is possible to reconstruct the molecular constitution from the value of its TI if its degeneracy is not too high; this solution of the ''inverse problem'' allows one to make predictions in QSARs.[137,138]

In 1982, Balaban developed the average distance connectivity index (J) based on distasums,[139] to reduce the degeneracy of previous indices (Equation 19).

$$J = \left[\frac{q}{\mu+1}\right] \sum_{ij} (d_i d_j)^{-1/2} \tag{19}$$

The numbers of graph edges, q, and of cycles in the graph, μ, are introduced into Equation (19) to avoid the automatic increase of J with graph size and cyclicity. Indeed, for an infinite linear carbon chain, it was demonstrated that $J = \pi = 3.14159$.[140] The nature of atoms can be taken into account by means of parameters based on their relative atomic numbers, electronegativities, or covalent radii, with respect to those of carbon atoms.[141]

A different approach to lowering the high degeneracy of some TIs such as the Wiener index was to make use of Shannon's formula in information theory, which uses base-two logarithms. The first such ''information theoretic indices'' were proposed by Balaban and Filip,[142] Bonchev,[143] Trinajstic,[144] and Basak et al.[145–147] The former types of indices consider separately the information on each class of summands. The latter indices include all atoms (hydrogens also) in the constitutional formula, and consider the information content provided by various classes of atoms.

Third-generation TIs are based on new, real-number LOVIs and, of course, must also be real numbers. Since the set of integers, although infinite, is smaller than the set of real numbers, such TIs have less chance to degenerate than previous ones. A matrix such as **A** or **D** can be converted into a system of linear equations whose unknowns are real-number LOVIs and whose coefficients are the matrix entries supplemented by two column vectors, which can convey chemical or topological

information; one vector replaces the zeros on the main diagonal, and the other vector provides the free terms of the equations. The result is a ''triplet TI'' denoted by the components of the triplet, namely, the matrix, the main diagonal vector, and the free term vector. Then the LOVIs may be assembled into a TI by various operations. Thus, AZV triplet LOVIs summed over all vertices yield the ''AZV topological index'', which correlates well with some physical properties of alkane hydrocarbons. **A** stands for the adjacency matrix, Z stands for the atomic number of each nonhydrogen atom, and **V** is the free term vector for the vertex degree. The combinatorial nature of the triplet combinations and assembly operations affords a large variety of TIs that may be adapted to different databases.[148]

Another type of LOVI results from applying information theory at the vertex level, providing an informational LOVI; then a formula similar to Randic's index (Equation 15) assembles such LOVIs into four types of TIs denoted by the letters U, V, X, and Y.[149]

The adjacency matrix **A** considers only nearest-neighbor interactions and is identical to the Hückel matrix in quantum chemistry; however, the LOVIs derived from the distance matrix **D** place the largest weight on the more distant vertices. In practice, chemical interactions are strongest between adjacent atoms, but more remote atoms also exert an influence that gradually decreases with the distance, as shown by the through-bond inductive effect. Matrices modeling this feature have been devised. One is the reciprocal distance matrix whose entries are reciprocal values of topological distances; the TIs based on this matrix are called *Harary indices*.[150,151] A different idea is to devise ''regressive distances'' or ''regressive vertex degrees'' by means of nonsymmetrical matrices whose entries in row i represent sums of topological distances or degrees, respectively, for vertices in shells around vertex i; an exponentially decreasing factor multiplies each successive shell. The results are indices that slightly change the distasum or the vertex degree, respectively, according to the molecular topology.[152,153]

Newer ideas for TIs involve the adaptation of TIs to the corresponding database; one can explore the optimal molecular descriptor for that database by allowing the exponent in the formulae for χ or J (Equations 15 and 19) to differ from $-1/2$,[154] or by computing, for each database, a new type of Randic's χ index in which the adjacency matrix has, on its main diagonal, variable numbers for each type of atom instead of zeros.[155]

Fourth-generation TIs are those that include information on stereochemical features of molecules. This type of TI is now being developed, and so far there has been only limited success for diastereomers and enantiomers.[74,156–159]

One should be aware that there are intercorrelations among TIs[160,161]; therefore, one should either eliminate collinearly correlated TIs using the statistical packages available for principal component analysis (PCA),[162] or one should use Randic's orthogonalization procedure for intercorrelated parameters.[163,164]

The great advantage of TIs is their ease of calculation for any imagined structure at low ''CPU (central processing unit) cost''. Many QSPR studies with TIs have been published, and they can be found in reviews[165–167] and in treatises on chemical graph theory.[144,168,169] To facilitate the computation of TIs, commercial programs such as CODESSA, POLLY, or MOLCONN are available.[170–172]

Recalling the lead optimization with 13 molecular descriptors[3] described in Section 1, it is now appropriate to provide details on these descriptors for the amino acids. Four of these descriptors were TIs: three Kier–Hall indices (ϕ, ${}^2\kappa_\alpha$, and χ^v) and Balaban's J index. Other parameters were the lipophilicity (log P) calculated according to Ghose and Crippen,[96] the ellipsoidal and molar volumes, the MR, and the dipole moment. The remaining four descriptors were simple numerical data for the numbers of atoms (oxygen, nitrogen) or groups (ethyl, hydroxyl). The conclusion that one may draw from this approach confirms Katritzky's favorable assessment of the value of TIs used together with other descriptors for QSAR studies,[79] and contradicts criticisms about using TIs in QSARs.[49] If TIs prove their utility for peptides whose stereochemistry is so important, then it is even more likely that they will work (together with other descriptors) for peptidomimetics or any other smaller molecules in drug design.

9 THREE-DIMENSIONAL SHAPE DESCRIPTORS

Surpassing the fourth-generation TIs, a series of shape descriptors has been reported in the literature. The rapidly increasing performance of computers now makes it possible to perform elaborate calculations for quantum-chemical parameters.[168,173] The approach initiated by Mezey has allowed shape simulations to be made for various biologically important molecules such as amino acids or even macromolecular compounds.[79,174–176]

The most promising of all the 3-D/QSAR methods is comparative molecular field analysis (CoMFA).[22,177–180] A 3-D grid is defined so as either to (i) include the most active or the most rigid pharmacophore (ligand), or (ii) model the receptor cavity defined by its molecular docking with the potential bonding sites. Calculations are carried out at each intersection point of the

imaginary grid using force-field (molecular mechanics) methods or Gaussian approximations, Lennard-Jones potentials for noncovalent ligand–receptor interactions, and Coulomb electrostatic attractive/repulsive forces. Statistical evaluations are carried out by using partial least squares (PLS) and PCA.[162] Cross validation is achieved by the leave-one-out procedure from the studied series, and the error is measured by a parameter named *PRESS* (*predicted residual sum squares*). The most difficult problems in CoMFA studies are connected with conformational aspects of flexible molecules and with molecular alignment.

The growing literature on CoMFA has been reviewed, and is too elaborate to be presented here in more detail.[50,53–60,67] For just the brief period between 1993 and 1997, the bibliography on CoMFA has 383 references.[59]

Other descriptors that have been developed include the 3-D/WHIM (three-dimensional/weighted holistic invariant molecular) and G-WHIM (grid-weighted holistic invariant molecular) descriptors,[51] which encompass size, shape, symmetry, and atom distribution, as well as the EVA descriptor,[52] derived from the vibrational frequencies; all of these are independent of structural alignment. Further methods related to CoMFA are HASL (hypothetical active site lattice),[181] and CoMMA (comparative molecular moment analysis), which is independent of the dilemmas raised by molecular superposition.[182] As discussed in section 10, similarities and dissimilarities between aligned molecules can be detected by means of CoMSIA (comparative molecular similarity indices analysis).[60]

10 MOLECULAR SIMILARITY AND DISSIMILARITY

Molecular similarity is important when examining potential candidates for enzyme inhibitors, because inhibitors usually fit into the receptor cavity of the enzyme in the same way as the natural substrate, but their structural difference leads either to irreversible bonding or an intermediate that is no longer able to participate in subsequent reactions. A classical example is that of sulfonamides that mimic *para*-aminobenzoic acid (PAB) and thus act as bactericides. Among the numerous other examples are the anticancer agent 5-fluorouracil, and acyclovir or zidovudine (azidothymidine (AZT)) as anti-AIDS (acquired immune deficiency syndrome) viral agents; in these examples, the drugs mimic pyrimidine or purine bases essential for nucleic acid replication. On the other hand, molecular dissimilarity (diversity) is important when looking for lead compounds in a large database such as the Cambridge Structural Database (X-ray crystallographic data) or the National Cancer Institute Databases, because one wishes to have as much structural variation as possible.

Several books have been dedicated to this topic. TI can also be used for this purpose.[183] Here, we discuss only the more recent developments.

For substructure searches, Burden[184] suggested using molecular identification numbers obtained from the two lowest EVAs (and occasionally eigenvectors) of a connectivity matrix **B** obtained from the hydrogen-depleted graph; the diagonal element b_{ii} is the atomic number of atom i; entries b_{ij} are 0.1, 0.15, 0.2, and 0.3 for single, aromatic, double, and triple bonds, respectively, between connected atoms i and j, and 0.01 otherwise; endpoints (vertices with degree 1) are distinguished by augmenting their b_{ij} entry by 0.01. Over 20 000 structures have been successfully tested and discriminated, with the two lowest EVAs taken to 16 decimal places. A further step was undertaken by Pearlman[185] who proposed the BCUT (Burden–Chemical Abstracts–University of Texas) approach, which consists of taking the lowest and highest EVAs, but using modified matrices: instead of atomic numbers, more relevant data for intermolecular interactions are inserted on the main diagonal, namely, atomic charges, polarizabilities, and H-bond donor and acceptor abilities (corresponding to electrostatic, dispersion forces, and hydrogen bonding, respectively). Using the program CONCORD[186] to generate 3-D structures from 2-D (two-dimensional) structures, it is possible to introduce properly scaled information on the 3-D structure as the off-diagonal entries. With their ''autochoose'' algorithm, Pearlman et al.[186] obtained a robust program for comparing the diversities of large databases at a relatively low CPU cost.

A seductive and fairly fruitful approach to drug design was made possible by rapid advances in hardware. It involves interactive computer graphics,[10–14] and benefits from the fact that color on a computer screen is free, unlike color in print. This is a powerful argument in favor of electronic publishing; the future of information processing has been changed by the computer as much as by Gutenberg several centuries ago; and the ''information superhighway paradox''[187] will probably be solved in the very near future by electronic publishing.

Like 3-D physical models of molecules, computer simulations may be seen, rotated, and moved around, but, in addition, they offer many advantages:

- the geometry (interatomic distances, bond angles, torsion angles) determined by analytical methods can be accurately reflected by the model;
- the molecular energy can be calculated for any real or imagined conformation either by molecular

mechanics (force field) calculations or by semiempirical quantum-chemical methods (ab initio methods are still too CPU-costly for all but small molecules);
- these calculations indicate which is the ground-state conformation and how much energy would be needed to change it so that it would fit the receptor cavity;
- several computer models can be superimposed to afford a 3-D image of the supermolecule and of the excluded or included volume;
- molecular docking may be simulated and dynamic approaches can be programmed.

Among the usual modes of presenting stereodrawings in color, one of the easiest to visualize is to depict the molecular contours with dots (short vectors) because one may see what lies behind the surface and one may include the molecular skeleton inside this surface; alternatively, wire, ball-and-stick, or space-filling molecular models may be imitated. Some of these models are slow to draw and therefore are not appropriate for interactive real-time graphics. Expensive computers already exist, which allow the molecular designer to view molecular models stereoscopically with polarized eyeglasses (as in 3-D movie theaters) and to manipulate them with a trackball. Chemists hope that programmers will soon be able to produce holograms, which could also be handled in print.

11 CASE STUDIES OF QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIPS

Dihydrofolate reductase (DHFR) is an important enzyme, present in all organisms, from bacteria and protozoa to plants, animals, and humans. Folic acid **(1)** is a vitamin for humans, and when it is present in insufficient amounts during pregnancy, severe malformations of the central nervous system occur. It consists of three ''building blocks'': pteridine, PAB, and L-glutamic acid. Bacteria (but not humans) synthesize DHFR using PAB and therefore when sulfonamides (sulfa drugs) are present, these mimic PAB and block the synthesis of **(1)** by acting as selective bactericides. Methotrexate **(2)** is a powerful inhibitor of DHFR, and acts as anticancer agent, preferentially attacking rapidly proliferating cells. The dihydro derivative of folic acid **(3)** is reduced by DHFR, affording tetrahydrofolic acid **(4)**, which is able to react with formaldehyde in vitro or with serine in vivo yielding the five-membered ring intermediate **(5)**. This compound reacts in many single carbon transfer reactions, such as the methylation of deoxyuridylate affording thymidylate (thymine is one of the four bases in DNA), and in amino acid syntheses.

(**1**)

(**2**)

(**3**)

(**4**)

(**5**)

Other medically useful inhibitors of DHFR, in addition to methotrexate, are the antibacterial trimethoprim (**(6)**, $R = \mathrm{OMe}$), the anticoccidial diaveridine (**(6)**, $R = \mathrm{H}$), employed in veterinary practice for ''egg and poultry factories'', and the antimalarial pyrimethamine **(7)**.[14]

(**6**)

The amino acid homology in the primary structure of DHFR isolated from various species is high when comparing vertebrates among themselves, but low when

(7)

comparing vertebrates to bacteria or bacteria among themselves. Binding of the substrate occurs through a combination of hydrogen bonding, electrostatic, and hydrophobic forces. The selectivity originates in subtle differences among these forces, which determine the geometry of the association between enzyme and ligand.

Equation (20) is one of the QSAR equations for the inhibition of bovine liver DHFR by trimethoprim analogs[188,189]:

$$\log\left(\frac{1}{C}\right) = 0.62(\pm 0.13)\pi_{\text{meta}} + 0.33(\pm 0.18)\sum\sigma + 4.99(\pm 0.07) \quad (20)$$

where $n = 23$, $r = 0.931$, and $s = 0.146$.

The hydrophobicity term of one meta-substituent of the benzyl group in analogs of **(6)** has the largest coefficient; the $\sum\sigma$ term includes the electronic contributions of substituents in the benzylic ring. For other vertebrates, including humans, the QSAR equations are nonlinear, but not much different. On the other hand, the inhibition of *Escherichia coli* DHFR (a bacterial enzyme) is expressed by Equation (21)[190,191]:

$$\log\left(\frac{1}{K_i}\right) = 1.38(\pm 0.30)\text{MR}_{3,5} + 0.82(\pm 0.35)\text{MR}_4 + 5.77(\pm 0.25) \quad (21)$$

where $n = 23$, $r = 0.918$, and $s = 0.250$.

Reliable and accurate apparent inhibition equilibrium constants K_i express the biological activity; the $\text{MR}_{3,5}$ and MR_4 terms are truncated MR values of the substituents in the meta and para positions of the benzyl ring, respectively.

Equation (22) represents another equation for the same bacterial enzyme[62]:

$$\log\left(\frac{1}{\text{IC}_{50}}\right) = 0.72(\pm 0.27)\sigma_{\text{para}} + 8.85(\pm 0.16) \quad (22)$$

where $n = 11$, $r = 0.892$, and $s = 0.185$

Here the biological activity is expressed by the less accurate IC_{50} (50% inhibitory concentration) values. The differences between Equations (20), (21), and (22) reflect the fact that hydrophobic interactions are more important in vertebrate DHFRs, whereas polar interactions are more important in bacterial DHFRs.[14,62]

12 QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIPS IN ENVIRONMENTAL CHEMISTRY AND TOXICOLOGY

The toxicity of new chemicals is an integral part of drug design, since the therapeutic ratio contains toxicity in the denominator. In addition, the toxicity of chemicals released into the environment has become an important problem for present day civilizations. One may recall the case of organomercurials concentrated by marine organisms that led to casualties in Japan, the ''Silent Spring'' caused by DDT (1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)-ethane) and emotionally described by Rachel Carson in her well-known book, or the chemical accidents in Seveso (Italy) and Bhopal (India). The polychloro-dibenzodioxins released in the Seveso accident, which were also present in the defoliant (Agent Orange) used in the Vietnam war, as well as methylisocyanate, which caused many fatalities in Bhopal, are extremely and acutely toxic compounds. The less acutely toxic carcinogenic polycyclic aromatic hydrocarbons (PAHs) such as benzo[*b*]pyrene and benz[*a*]anthracene are, however, as dangerous when inhaled for a long time because they undergo oxidation in the liver to the corresponding epoxy-dihydroxy-tetrahydro derivatives at the ''bay-region'' benzenoid ring, and this ultimate carcinogen causes permanent damage to cellular DNA. Cigarette smoke as well as car exhaust gases have a significant content of such carcinogens. The Ames test is a quick means of determining mutagenic properties of chemicals, and it is inferred that there is a good correlation between mutagenic and carcinogenic activity.

The theoretical prediction of toxicities by means of QSARs is no longer wishful thinking, as stressed by Karcher and Devillers,[26] as well as by Basak.[29] Similarities between QSARs in CALD and in environmental sciences exist (Hansch approach, multivariate techniques) but the differences are more marked. In the latter sciences, the analyzed response is usually for the whole organism (although the target enzyme or organ is also relevant), the receptor and mechanism are seldom known, and the mechanism of action may be either specific or nonspecific. The aims of QSAR studies in these two fields are, of course, quite different: to find new drugs for human or veterinary use on the one hand and, on the other hand, to identify (and find ways of coping with) toxic wastes or to design pesticides.

Randic's TI $^1\chi$ was able to model soil sorption of PAHs by means of the ratio (K_{om}) between organic matter sorbed by the soil and dissolved in soil water, leading to

the QSAR shown in Equation (23)[28]

$$\log K_{om} = 0.53^1\chi + 0.43 \quad (23)$$

where $n = 72$, $r = 0.977$, $s = 0.282$, $F = 1478$, and $EV = 95.4\%$.

An early QSAR study of the toxicity (50% lethal dose, LD_{50}) of phenols for mice is shown in Equation (24)[192]:

$$\log\left(\frac{1}{C}\right) = 0.44(\pm 0.06)C\log P + 1.76(\pm 0.17) \quad (24)$$

where $n = 25$ and $r^2 = 0.894$.

Though the mechanism by which mice are killed is not clear, Equation (24) confirms Ferguson's principle mentioned in Section 5.

For the toxicity of aniline derivatives on mouse embryo fibroblast cells, the QSAR shown in Equation (25) was found[193]:

$$\log\left(\frac{1}{C}\right) = -0.55(\pm 0.19)\sigma^+ - 0.22(\pm 0.15)\log P + 4.07(\pm 0.222) \quad (25)$$

where $n = 20$ and $r^2 = 0.849$.

In the last two cases, comparison with QSAR equations for organic reactions provides indirect support that free radicals may be involved in the toxic effect.

A much-studied topic deals with aquatic toxicity for vertebrates such as fish (many studies involved fathead minnows, *Pimephales promelas*), single-cell eukaryotes such as *Tetrahymena pyriformis*, or gram-negative prokaryotes such as *Vibrio fischeri* (formerly *Photobacterium phosphoreum*). One can conduct either static tests in solutions of various concentrations, or dynamic (flow) tests, for diverse time intervals. Narcosis or respiratory uncoupling caused by phenols or anilines, and acute toxicity caused by various congeneric chemicals, have been effectively modeled by QSAR equations. In most cases, a large part of the variance is explained by log P values, indicating that the transport across biomembranes must be an important factor.

An example for acute toxicities (50% lethal concentration (LC_{50})) with rainbow trout for 96-h exposure to various pesticides such as orthophosphates, carbamates, aromatic halides is shown in Equation (26)[26]:

$$\log\left(\frac{1}{C}\right) = 0.288\log P + 1.56 \quad (26)$$

where $n = 14$, $r = 0.902$, $s = 0.195$, $F = 52.5$, and $P < 0.01\%$.

Mekenyan et al. considered a range of conformations for flexible molecules and devised QSAR equations for polychlorinated biphenyls, dibenzofurans, and dibenzo-*p*-dioxins in terms of quantum-chemical, topological, geometrical, and hydrophobic parameters.[76,194] For multiple conformations, the COREPA (common reactivity pattern) approach can be applied not only to toxicophores but also to pharmacophores.[195,196]

Experimental data for the basic toxicity of about 1500 high-production-volume chemicals is being carried out by about 200 US chemical and oil companies at high cost; the US Environmental Protection Agency has emphasized the need for observing new protocols that spare test animals. Evidently, any theoretical method that would provide reasonable guesses for the toxicity of the many thousands of chemicals produced in smaller amounts would spare considerable funds and effort.

13 STATISTICAL DATA AND COMPUTATIONAL APPROACHES

A few relevant literature data on chemometrics and statistics are provided briefly.[197] As mentioned earlier, PCA multiple regression and PLS are the methods of choice. Cluster analysis and pattern recognition techniques help in detecting similarity or diversity in databases of chemical structures. Two such techniques are the *k*-nearest neighbor (*k*-NN) method, and a class modeling technique called *SIMCA* (*similarity, chemistry, and analogy*), which places objects from a high-dimensional space into lower dimension boxes.[39] The DARC-PELCO method[168,169,198] originated from the idea that information is structured in successive layers around a focal point, and developed corresponding algorithms. The autocorrelation method was applied successfully by Devillers in QSAR for molecular modeling and in environmental sciences.[198]

For a QSAR that varies nonlinearly with structural parameters, newer and very efficient methods are artificial neural networks[199–203] and genetic algorithms,[204] which can be applied either separately, or more efficiently together.

14 CONCLUSIONS

Computational chemistry has reached a level of trustworthiness by producing valuable results in medicinal chemistry. Success stories for drug design were few until 20 years ago[205–207]; an early discovery based on QSARs was pralidoxime (2-pyridine-aldoxime methiodide, **(8)**, an acetylcholinesterase inhibitor, which removes phosphate from the serine residue of acetylcholinesterase in cases of

organophosphate or nerve gas poisoning). QSARs also contributed to the discovery of cimetidine **(9)**, as well as its furanic analog ranitidine **(10)** both of which are used for treating gastric ulcers as histamine agonists for H_2 receptors. Nowadays, the medicinal drugs obtained by means of QSAR, CALD, and molecular modeling studies are so numerous that even a nonexhaustive enumeration would be too long to include here. Only three newer examples of commercial drugs found with the contribution of QSAR studies will be included: the antibiotic norfloxacin **(11)**, the antihypertensive agent losartan **(12)**, and the antiviral drug indinavir **(13)** used for treating autoimmune deficiency syndrome, all benefited from the results of molecular mechanics and molecular simulation simulations based on X-ray diffractometry data.

(**8**)

(**9**)

(**10**)

(**11**)

(**12**)

Nowadays, every major pharmaceutical company has CALD (molecular modeling and computer-assisted ligand design) and combinatorial chemistry sections,

(**13**)

as well as proprietary databases. The tools of the trade are

1. molecular graphics and data visualization;
2. quantum chemistry at the ab initio and semiempirical levels MNDO (modified neglect of differential overlap), AM1 (Austin Method 1), and PM3 (parameterized method 3) for obtaining atomic charges, frontier orbital energies, and super-delocalizabilities;
3. molecular mechanics based on force fields and molecular dynamics;
4. molecular modeling and conformational searching on the potential energy hypersurface;
5. molecular structure databases for 2-D and 3-D structures or substructures, and criteria for similarity or dissimilarity;
6. QSARs and QSPRs using all the available panoply of molecular descriptors, from TIs to de novo (Free–Wilson) and Hansch's lipophilicity approaches, alternating computational and experimental stages for the determination of bioactivities in order to gradually improve the QSARs;
7. pharmacophore and receptor analysis using advanced statistical methods, such as artificial neural networks and genetic algorithms.

Hansch et al. recently wrote a fascinating book chapter, which should become a citation classic, since it opens many ''doors of perception'' and has many paragraphs and data worthy of being quoted.[63] In brief, the authors describe how their database of about 10 000 QSAR data (of which one-third are for biological/enzymatic systems and two-thirds for organic reactions) can be used to understand the chemistry of living cells, and thus to devise better drugs or pesticides. This chapter could become a gold mine for medicinal chemists and pharmacologists.

A few quotes from this last chapter (reproduced with permission of Taylor & Francis) are in order:

> The advent of ''sexy'' 3-D pictures of ligands bound to enzymes of established structure captured researchers' attention the way that the Lorelei of old entranced the sailors on the Rhein. Mechanism based on physical organic chemistry was forgotten .... Can SAR

> (structure–activity relationship) problems be solved de novo with 3-D pictures? Our belief is that mechanistic physical organic chemistry is on the verge of an exciting new venture in helping to elucidate chemico-biological interactions that will do vastly more than simply justify its existence to make only incremental advances in our study of the chemistry of life.

The authors of this chapter indicate how to mine their rich database for relevant, meaningful, and manageable information. Then, they show by example what one can learn from such data. By grouping together QSAR equations in terms of electronic and/or lipophilicity parameters, it becomes possible to gain insight into mechanisms of enzymatic reactions. Thus, the *signs and values* of the *slopes and intercepts* in such equations are powerful indicators of the similarities and differences between complicated biochemical reactions and simple reactions that are well understood mechanistically. As biological QSARs are more difficult and expensive (and frequently less precise and with smaller numbers of data) than physical–organic QSARs, ''lateral'' support by the latter can add confidence in the results of the former studies. Bridges must be built between these two strictly compartmentalized areas of research. Numerous examples are presented and discussed, and several suggestions for plausible mechanisms and for promising classes of new drugs are made in this chapter.

It seems appropriate to conclude with a few other quotations from this chapter:

> The rather abstract, ''boring'', multivariate equations have left many who stopped to think of the enormous complexity of the problem of formulating QSAR from a set of chemicals perturbing a cell or a mouse with the feeling that they were watching a con game ....
> The 3-D graphics distracted many from trying to relate biological QSAR to the much better understood mechanistic studies from the fields of physical, organic, and biochemistry. But the enormous driving force to understand how chemicals react with the various forms of life (and its constituent parts) and the economic prospects in terms of designing the billion-dollar drug as well as understanding toxicology, have been relentless encouragement for more and more researchers to attempt what some still regard as impossible .... Because there are virtually an unlimited number of organic chemicals and a huge number of biological systems (DNA, enzymes, organelles, cells, and whole organisms) with which they can interact, we must develop generalizations, limited as they may be, to be used in the planning stage of synthesis of the myriad chemicals we seem to need to facilitate our existence .... Our present system is a small start on the problem of the design and construction of a computerized means of keeping account of what has been done and how it can be used, but we are confident that it will grow rapidly.

ABBREVIATIONS AND ACRONYMS

AIDS	Acquired Immune Deficiency Syndrome
AM1	Austin Method 1
AZT	Azidothymidine
CADD	Computer-assisted Drug Design
CALD	Computer-aided Ligand Design
CAMD	Computer-aided Molecular Design
CAS	Chemical Abstracts Service
CoMFA	Comparative Molecular Field Analysis
CoMMA	Comparative Molecular Moment Analysis
CoMSIA	Comparative Molecular Similarity Indices Analysis
COREPA	Common Reactivity Pattern
CPU	Central Processing Unit
DDT	1,1,1-Trichloro-2,2-bis(*p*-chloro-phenyl)-ethane
DHFR	Dihydrofolate Reductase
EVA	Eigenvalue
G-WHIM	Grid-weighted Holistic Invariant Molecular
HASL	Hypothetical Active Site Lattice
HPLC	High-performance Liquid Chromatography
IC_{50}	50% Inhibitory Concentration
k-NN	*k*-Nearest Neighbor
LC_{50}	50% Lethal Concentration
LD_{50}	50% Lethal Dose
LFER	Linear Free-energy Relationship
LOVI	Local Vertex Invariant
MNDO	Modified Neglect of Differential Overlap
MR	Molar Refractivity
MSD	Minimal Steric Difference
MTD	Minimal Topological Difference
NMR	Nuclear Magnetic Resonance
PAB	*para*-Aminobenzoic Acid
PAH	Polycyclic Aromatic Hydrocarbon
PCA	Principal Component Analysis
PLS	Partial Least Squares
PM3	Parameterized Method 3
PRESS	Predicted Residual Sum Squares
QSAR	Quantitative Structure–Activity Relationship
QSPR	Quantitative Structure–Property Relationship
SAR	Structure–Activity Relationship
SIMCA	Similarity, Chemistry, and Analogy
TI	Topological Index
UV	Ultraviolet
2-D	Two-dimensional
3-D	Three-dimensional

3-D/WHIM Three-dimensional/Weighted Holistic Invariant Molecular

Laboratory robotics is being increasingly applied in pharmaceutical development to help meet the needs of increasing productivity, decreasing drug development time and reducing costs. A robot can be defined as a device that can perform a variable but programmed series of physical manipulations including moving objects, sample identification, weighing, extraction, filtration and dilution. Robots can be classified according to the type of movement the robotic arm can perform. Three of the most common geometries for laboratory robots are: Cartesian (three mutually perpendicular axes); cylindrical (parallel action arm pivoted about a central point); and anthropomorphic (multijointed, human-like configuration). Each has been used in the pharmaceutical industry with varying degrees of success. Cylindrical and anthropomorphic robots generally provide more flexible ''human-like'' automation that includes transfer, weighing, extraction and filtration of samples.

In a typical analysis, four major steps are performed: sampling; sample preparation; sample measurement; and data collection/analysis/reduction to provide a report for the customer. Most laboratory robotic systems are employed to automate the sample preparation stage which is normally the most labor-intensive step of the analysis process. Automation has been applied in pharmaceutical analysis in a number of areas: raw materials release; in-process testing; release of finished products; and stability testing of the dosage form. In pharmaceutical analysis the assay, content uniformity and dissolution tests are the most common methods that use automation. Developing an automated assay or content uniformity method for a dosage form requires several aspects to be investigated before validation of the procedure can proceed, including: extraction; filter; carry-over studies; and stability of solution.

Validation can be defined as establishing documented evidence which provides a high degree of assurance that a specific process will generate a product, in our case an automated method, that will meet predetermined specifications and quality attributes. Qualification is part of validation and has been defined for installation, operation and running of the system under workload for a specific application. In the pharmaceutical industry the ''4Qs'' model is generally used to qualify the unit. Validation of manual analytical methods is well understood but documented in a number of guidelines in slightly different ways. It has been only recently that single documents (International Conference on Harmonisation) have emerged that describe the terminology and methodology for method validation. For robotic methods, equivalency between the manual and automated procedure is an important extra validation test that is often performed since it is unusual not to have a manual already in use. This test may not be relevant if accuracy has been also demonstrated for the automated method. For successful transfer of automated methods, the robotic systems used in research and development (R&D) should mirror those used at the commercial production site. The automated equipment must be rugged and easy to use for the production quality control (QC) laboratory to invest in the technology. Complex robotic systems that need specialist, dedicated staff, have not been generally successful in the QC laboratory.

Robotic systems are a high capital cost and this is often justified by increasing throughput since automatic systems can operate 24 h a day and over weekends unattended, thereby also reducing the cost per analysis. During the 1990s, drug development times have significantly reduced, which has required more responsive ''just-in-time analysis'' and this has been an integral part of cost reduction for the release of raw materials and commercial products. Automated systems also enable scientists to use their time more productively by spending time on evaluating data and on more innovative tasks rather than performing routine repetitive operations.

Although the application of laboratory robotics is increasing, limitations including high capital cost, relative complexity of operation and poor connectivity between the robot and laboratory information management systems, are hindering its implementation.

1 INTRODUCTION

Laboratory robotics is being increasingly applied in pharmaceutical development to help meet the needs of increasing productivity, decreasing drug development time and reducing costs. A robot can be defined as a device that can perform a variable but programmed series of physical manipulations,[1] including moving objects, sample identification, weighing, extraction, filtration and dilution. Robots can be classified according to the type of movement the robotic arm can perform.[2] Three of the most common geometry's for laboratory robots are: Cartesian (three mutually perpendicular axes); cylindrical (parallel action arm pivoted about a central point); and anthropomorphic (multijointed, human-like configuration). Each has been used in the pharmaceutical industry with varying degrees of success. The PAL system manufactured by CTC Analytics and shown in Figure 1 is an example of a Cartesian robot that performs dedicated relatively simple tasks such as sample dilution, mixing and filling a loop of an autoinjector with a fixed volume of solution for sample analysis. Cylindrical and anthropomorphic robots generally provide more flexible ''human-like'' automation that includes transfer, weighing, extraction and filtration of samples.

In a typical analysis four major steps are performed: sampling; sample preparation; sample measurement; and data collection/analysis/reduction to provide a report for the customer. Most laboratory robotic systems are employed to automate the sample preparation stage which is normally the most labor-intensive step of the analysis process. The results of one survey[3] (Figure 2) indicated that about 60% of the analysis time is spent on sample preparation.

Figure 1 Photograph of a CTC Analytics PAL system. (Reproduced by permission of CTC Analytics AG.)

Figure 2 Breakdown of time spent on key steps in sample analysis process.

Automatic analyses often involve similar steps to the manual procedures but robots have an important advantage of performing these repetitive tasks accurately and precisely for long periods of time without the need for breaks. A key benefit is higher productivity,[4] improved quality in terms of increased accuracy and precision of the data generated. Furthermore, automation also frees up analysts' time for important activities such as data interpretation and more innovative tasks. Unattended analysis also reduces the exposure of the scientists to hazardous chemicals.

Although the application of laboratory robotics is increasing, limitations including high capital cost, relative complexity of operation and poor connectivity between the robot and laboratory information management systems, are hindering its implementation.

2 HISTORY

Considerable effort has been devoted over the past decades to increasing the analysis speed and as well as to improving data handling and report generating software. In contrast, automation of sample preparation has lagged behind in its development. Early examples of laboratory automation include continuous flow analyzers,[5] flow injection analysis,[6] and automatic titrators. With the development of inexpensive microelectronics and microcomputers, it is possible to build flexible and more

Figure 3 Diagram of the evolution of laboratory automation.

Figure 4 Photograph of Zymate laboratory robot. (Reproduced by permission of Zymark Corporation.)

sophisticated automated systems. These developments have led to programmable laboratory robots that perform a series of physical manipulations using some form of mechanical arm. The deployment of these devices has had a major impact on how routine laboratory tasks are performed. A diagram illustrating the evolution of automation is shown in Figure 3.

The first robotic instruments were introduced into the pharmaceutical laboratory in the early 1980s. The Zymate cylindrical robot (Figure 4) typified these systems. This robot is a modular system that uses its own programming language, scheduler and a range of accessories to automate a wide range of pharmaceutical analytical procedures including dissolution testing and tablet processing. At that time the main competitor was Perkin-Elmer's MasterLab which employed a Mitsubishi robot, an electronics module and associated communications interfaces that enabled the system to be controlled by a high-level menu-driven programming language. This robot used anthropomorphic arm geometry with five axes of motion. During the last 10 years many other manufacturers including CRS Robots, Sands Technology, Source for Automation, Novi and Hewlett-Packard ORCA (Optimized Robot for Chemical Analysis), to name but a few, have developed laboratory robotic systems. Although these robots are laboratory based they are relatively large systems that require their own specially designed bench area and dedicated scientists to develop and maintain the equipment. To overcome these disadvantages and to enhance reliability, smaller, more dedicated systems have now been developed that are simpler robotically and are controlled by easy-to-use menu-driven programs. An example of this smaller, bench-sized robot is Zymark's Benchmate Tablet Processing Workstation. There is now also a trend towards automation that does not use a robotic arm but instead employs dedicated accessories to perform tasks like dissolution testing. A good example of this type of automation is Source for Automation's Automated Dissolution Module. This equipment has the added advantage of being scalable such that single or multiple dissolution units can be linked and controlled by one computer. These smaller automation systems are also more amenable to operating at-line in the production area and this, combined with the recent development of rapid non-invasive methods of analysis such as near infrared, provides the capability of generating analytical results within the manufacturing process.

3 PHARMACEUTICAL APPLICATIONS

Laboratory automation has been applied in pharmaceutical analysis in a number of areas. A summary of the basic steps in the production of a dosage form is given in Figure 5. The individual components that are used to formulate the dosage form need to be tested against a specification before the material can be released for the manufacture of a dosage form. The excipients

Figure 5 Diagram of the pharmaceutical analysis steps supporting the dosage form production process.

(nonactive ingredients) that give the formulation its fundamental properties, and the drug, must be tested against predefined specifications. Most excipients used have monographs in the United States or European pharmacopeias and involved traditional wet chemical methods. A comprehensive review of the application of flow injection analysis to automating wet chemical methods has published by Betteridge.[7] The heavy metals test, which is a fundamental test for many materials, has been automated using flow injection analysis.[8]

A key element of building quality into the manufacturing of a product is being able to obtain information on the state of the process while it is running. During the 1990s this has started to be addressed in the pharmaceutical industry. Rapid, rugged, reliable and ideally noninvasive analytical techniques are required to provide this information. Conventional laboratory robots have been developed to analyze powders,[9] using high-performance liquid chromatography (HPLC), from blending operations in solid dosage form manufacture.[10] Automation using noninvasive methods such as near infrared has been successfully developed by Sekulic et al.[11] to provide in-process control information. A comprehensive review of the application of near infrared to pharmaceutical analysis has been performed by Blanco et al.[12]

Following the manufacture of a drug product there is a need to ensure the equipment used is clean before the next manufacture can commence. Scypinski et al.[13] automated the analysis of cleaning samples employing the Zymark Benchmate workstation.

Drug products are released by checking the batch against a predefined specification. The most common specification tests include determination of the assay, degradation products, content uniformity and dissolution of the drug product. Content uniformity is a high-volume repetitive test in which the sample preparation has been automated using the Zymate Tablet Processing Workstation by Barrett,[14] Lagade et al.[15] and Sadlowski et al.[16] More recently, Stanley and Park[17] compared the Zymark Tablet Processing Workstation II and the Waters Tablet Processing System robots using content uniformity determinations. Drug content and degradation product determinations have also been automated by Stanley.[18] Metered dose inhaler (MDI) product analysis is highly labor intensive. Robotic systems have been developed by Monk[19] to provide a repeatable method of handling and firing the MDI product into a collection apparatus, measuring weight loss and dosage content determination. The Anderson impactor is well established for measuring particle size in MDIs and a robot to automate this process is shown in Figure 6.

There has been an increased demand for dissolution testing for solid oral dosage forms. One of the first totally automated dissolution methods was developed by Kostek et al.[20] in which the robotic dissolution system was coupled with an ultraviolet/visible (UV/VIS) spectrophotometer equipped with an on-line flow cell for real-time collecting of samples and the immediate acquisition of data. With complex matrices of drug products, some automated methods needed to have samples collected off-line for analysis;[21] Rios et al.[22] used flow injection analysis and Kostek et al.[23] used real-time HPLC analysis. With the development of fiber optics Kostek et al.[24] have applied the technology to enable the UV/VIS analysis to be performed in situ. Doddapaneni et al.[25] proposed an alternative approach for dissolution testing of nonroutine formulation development samples by employing a segmented strategy using an automated dissolution system

Figure 6 Diagram of a Novi robotic system for automating the Anderson impactor. (Reproduced by permission of M.P. Smith.)

linked to several fraction collectors/dilutor dispensers with an off-line UV/VIS spectrophotometer. Stability testing of finished product forms a major part of the workload in a pharmaceutical development laboratory and this is likely to increase with globalization in the pharmaceutical industry.[26]

4 SYSTEM DEVELOPMENT AND INSTRUMENT QUALIFICATION

Robotic systems produced in the early 1990s were flexible and could be configured to perform a variety of sample preparation tasks. These instruments were developed in a time when validation requirements for computerized equipment were less stringent. As a consequence the effort and time to implement these systems was significantly less than that required now as we move into the next millennium. Manufacturers have responded by producing smaller, more dedicated automated systems that are easier to validate and use. An example is the evolution from the Zymate robot to Benchmate-type systems by Zymark Corporation.

Equipment vendors and users have worked together to share the task of equipment qualification and validation. Validation can be defined as establishing documented evidence which provides a high degree of assurance that a specific process will generate a product, in our case an automated method, that will meet predetermined specifications and quality attributes. Qualification is part of validation and has been defined by the US Pharmaceutical Manufacturers' Association Computer System Validation Committee for installation, operation and running of the system under workload for a specific application. In the pharmaceutical industry the ''4Qs'' model is generally used to qualify the unit and this is outlined in Figure 7.

The Pharmaceutical Analytical Sciences Group in the UK has developed guidelines[27] on the requirements for the qualification of analytical equipment. Design qualification is meant to ensure that the equipment meets the purchaser's specification and conforms to a recognized quality standard (e.g. ISO Standard 9001). The vendor should also allow the purchaser access to the software source code and validation documentation. Under design qualification a system of change control for system upgrades also needs to be in place. Protocols should also be provided by the manufacturer for the installation, operational and performance qualification stages. Installation qualification is designed to ensure the automated system that you receive is what you ordered. The environmental conditions for the location of the robot should also be checked to make sure they are appropriate. The equipment is assembled, generally by the vendor, and the system switched on. Individual units of the robot, for example balances, homogenizers, diluters and filtration devices, are checked against the manufacturer's specifications at the operational qualification stage. Calibration checks (e.g. for balances) should be made using traceable standards. Finally, the performance qualification involves checking that all the units that make up the robot function correctly as a complete system. A typical method is run at this point to facilitate this performance check.

Figure 7 Diagram of ''4Qs'' model.

Software provided with the automated system should be developed using a life cycle management approach and according to a quality standard (e.g. ISO Standard 9003). The vendor should also provide certified evidence that the software has been validated (e.g. TickIT[28]).

Although a lot of effort is required to validate an automated system in the highly regulated environment of the pharmaceutical industry, for the most part, this makes good business sense and helps ensure complex automated equipment operates in the way in which it was intended.

5 METHOD DEVELOPMENT

In pharmaceutical analysis the assay, content uniformity and dissolution tests are the most common methods that use automation. Developing an automated assay or content uniformity method for a dosage form requires several aspects to be investigated before validation of the procedure can proceed.[29] The efficiency of the extraction step with respect to composition and pH of the extraction solvent together with, if used, the homogenization conditions of speed and time need to be studied. To optimize these factors efficiently, an experimental design (Figure 8) can be used to map the response surface of the extraction profile.

Suitable studies should also be conducted on the filter membrane to ensure significant quantities of drug are not retained and demonstrate that extractables from the filter do not interfere with the assay. The capacity of the filter to retain the filtrate without blocking is also important to enable the robotic system to work reliably. Automated sample preparation systems typically dispense solvents and perform dilutions gravimetrically.

Figure 8 Experimental design used for extraction studies.

Consequently, the density of each sample solution that is manipulated gravimetrically is needed to ensure volumetric requirements of the manual method are met. A robotic method usually performs analysis serially using common components such as extraction vessels and tubing. Carry-over of drug from one sample to the next must, therefore, be investigated typically by employing a sample containing no drug (blank). If a homogenizer is used to grind and extract a dosage form, the volume of solvent retained by the homogenizer probe should be determined to see if this is significant. A robotic system comprises many components that come into contact with the drug and extraction solvent, consequently checks need to be carried out to ensure extractables are not leached from the equipment and significant amounts of drug are not absorbed by the system (e.g. tubing). Stability of solution must also be investigated to ensure that not only is there satisfactory chemical stability but also there is acceptable physical stability in terms of evaporation of the sample and standard solution.

6 METHOD VALIDATION

Method validation should only occur after the method has been developed and optimized. It provides an assurance of the reliability during normal use and it can be described as the means of providing documented evidence that the method performs in the manner in which it was intended. Validation of manual analytical methods in the pharmaceutical industry is well understood but documented in a number of guidelines in slightly different ways. It has been only recently that single documents have emerged that describe the terminology and methodology for method validation.[30,31] The parameters investigated, together with their definitions, are summarized below.

1. Accuracy – closeness of agreement between the true or reference value and the value found.
2. Precision – closeness of agreement between a series of measurements obtained from multiple samplings of the same homogeneous sample.
   (a) Repeatability – precision under the same operating conditions over a short interval of time.
   (b) Intermediate precision – precision within laboratories: different days, analysts and equipment.
   (c) Reproducibility – precision between laboratories
3. Linearity – ability (within a given range) to obtain tests results which are directly proportional to the concentration (amount) of analyte in the sample.
4. Range – interval between the upper and lower concentration (amounts) of analyte for which the method has suitable precision, accuracy and linearity.
5. Specificity – ability to assess unequivocally the analyte in the presence of components of the matrix.
6. Quantitation limit – lowest amount of analyte in a sample that can be quantitatively determined with suitable precision and accuracy.
7. Detection limit – lowest amount of analyte in a sample that can be detected but not necessarily quantitated as an exact value.
8. Robustness – capacity of a method to remain unaffected by small, but deliberate, changes in method parameters. Provides an indication of the method's reliability during normal usage.

It has been recognized that not all the parameters described above are tested for each type of analytical method. The type of method and its intended use dictate which tests should be investigated. The scheme recommended by the *United States Pharmacopeia*[32] for assay validation is shown in Table 1.

For robotic methods equivalency between the manual and automated procedure is an important extra validation test that is often performed since it is unusual not to have a manual procedure already in use. This test may not be relevant if accuracy has also been demonstrated for the automated method. In addition, the test for intermediate precision for an automated method may not be appropriate to investigate since a robot should not be affected by analyst-to-analyst or day-to-day variability.

The validation parameters above, combined with the data generated during method development, provide

Table 1 *United States Pharmacopeia* data elements required for assay validation

Validation parameter	Assay for major component	Assay minor component (e.g. impurity)		Assay[b]
		Quantitative	Limit test	
Accuracy	Yes	Yes	[a]	[a]
Precision	Yes	Yes	No	Yes
Specificity	Yes	Yes	Yes	[a]
Detection limit	No	No	Yes	[a]
Quantitation limit	No	Yes	No	[a]
Linearity	Yes	Yes	No	[a]
Range	Yes	Yes	[a]	[a]
Ruggedness[c]	Yes	Yes	Yes	Yes

[a] May be required, depending on the nature of the test.
[b] Performance characteristic (e.g. dissolution).
[c] *United States Pharmacopeia* definition – degree of reproducibility of results under a variety of conditions expressed as percentage relative standard deviation.

the necessary assurance that the method will perform satisfactorily when used by trained analysts.

7 TECHNOLOGY TRANSFER

Technology transfer from R&D to a commercial site is a key step in the pharmaceutical development process. The technology involved is not only the manufacturing process for the dosage form but also the associated analytical methods to control the quality of the product.[33] These methods include assay, content uniformity of individual dosage units, degradation profile for the drug and dissolution methods. In the pharmaceutical industry validated methods must be transferred. The transfer process for analytical methods can range from repeating some of the validation tests, for example, linearity, accuracy and precision, to just repeating the analysis of several lots of well-characterized batches of drug product. If an automated method is available then there is usually an associated manual method. In this case there are a number of options for technology transfer and these include transfer of both the manual and automated method or just the latter.

For successful implementation of automated methods, the robotic systems used in R&D should mirror those used at the commercial production site. The automated equipment must be rugged and easy to use for the production QC laboratory to invest in the technology. Complex robotic systems that need specialist, dedicated staff have not generally been successful in the QC laboratory. For manual methods, the transfer tests not only the methodology but also the analysts that use the method. However, when transferring an automated method between robots of the same type, less validation may be required, provided that the equipment has been qualified.[34] If there is confidence that the two robots are validated then just an electronic transfer of the method may be possible, which represents a considerable reduction of effort. Typically, repeat analysis of at least one batch of each strength of drug product is carried out on both automated systems. The data can be compared statistically; however, this can result in false conclusions particularly when the two data sets have high precision. This scenario can lead to statistical differences that are not analytically significant. The acceptance criteria for comparison of methods should, therefore, include an absolute difference (%) between the means of the two sets of results.[34] Successful technology transfer hinges on good communication between the analyst(s) that developed the method and the laboratory that receives the procedure.

8 BUSINESS BENEFITS

A key goal for pharmaceutical businesses during the 1990s has been reducing the time to develop a product and get it to market. This benefit also means that the time it takes to find the compounds that will not be commercialized is decreased. From a business viewpoint this is equally important in that the time and money can be re-allocated to developing more new chemical entities.

The increasing cost of drug development and loss of sales that can occur if the drug is delayed, by as little as a day, is very significant for a billion-dollar-a-year product. Automation is playing an important role in helping to reduce the time to market and can be justified in many ways.[35] Robotic systems usually are a high capital cost and this is often justified by increasing throughput, since automatic systems can operate 24 h a day and over weekends unattended, thereby also reducing the cost per analysis.[36] During the 1990s drug development times have significantly reduced, which has required more responsive ''just-in-time'' analysis and this has been an integral part of cost reduction for the release of raw materials and commercial products. Robots perform operations highly reproducibly without getting tired, which should improve the quality of the data. Automated systems also enable scientists to use their time more productively by spending time on evaluating data and on more innovative tasks, rather than performing routine repetitive operations. Robotic systems also have the capability of storing an audit record of manipulations performed by the system, so if an unexpected result occurs when the instrument is working unattended, it

should be possible to find out when and what happened. This provides a high level of regulatory compliance. When analyzing hazardous materials, automated systems reduce the exposure of the operator to these substances. Robotic systems can also effectively smooth out peaks and troughs in work loads that without automation could result in staff working longer hours, introducing shift work or contracting out the extra samples. These benefits more than offset the initial capital cost of the robot, and return on investment is typically less than 2 years for most applications.[35]

ACKNOWLEDGMENTS

I would like to thank Chris Banton, Les Brockhurst, John Gostick and John Stanley, who have worked with me over several years, for their enthusiasm and support in implementing automated methods.

Solid-phase extraction (SPE) using small cartridges filled with sorbents of a small particle size has rapidly established itself as an important sample clean-up technique. It has prospered at the expense of liquid–liquid extraction (LLE) which is considered labor intensive and frequently plagued by problems, such as emulsion formation and use of large volumes of hazardous solvents. A remarkable characteristic of SPE is its easy adaptation to on-line mode by column switching techniques; switching can be effected manually or by automated controllers.

The same analyte/sorbent interactions that are exploited in liquid chromatography (LC) are of use in SPE, but particle sizes employed are greater. Chemically bonded silica (SI), usually with C_{18} and C_8 organic groups, is by far the most commonly used material. At present, cross-linked polystyrene and other polymeric resins and mixed-mode SPE sorbents are finding increasing use. A guide to improve sample clean-up procedure can be established.

There are different approaches to automation for both off-line and on-line SPE, which involve different levels of apparatus cost. SPE is generally easier and cheaper than LLE. The precision obtained is similar for both techniques, while the recoveries obtained by SPE are generally better than those obtained by LLE.

Enrichment and derivatization can also be carried out by use of sorbents as supports.

1 INTRODUCTION

In order to understand the place of SPE or other sample clean-up procedures in the pharmaceutical field, the drug evolution cycle should be considered. This can be divided into different steps: discovery; chemical process development; metabolism, bioavailability and pharmacokinetics; formulation studies; stability studies; toxicology and safety testing; commercial production and marketing. This cycle gives different kinds of samples that may need a pretreatment prior to their measurement. These pharmaceutical samples are bulk-drug, preformulations, formulations and biological samples. The last samples are also connected with topics such as therapeutic drug monitoring and toxicological analysis developed in many cases in the pharmaceutical field.

Nonvolatile species can be removed from either solid or liquid matrices by a number of techniques which range from distillation to dialysis, LLE, and SPE, including both ion exchange and sorption. The traditional LLE method as a sample clean-up procedure for *pharmaceutical samples*, has been superseded by SPE. This approach with porous solid particles (Rohm and Haas Amberlite XAD™ resins) goes back to the early 1970s.[1] Practical use of this method was undoubtedly hindered by the necessity of grinding, sizing and purifying the early XAD™ resins. Now, with the ready availability of pure bonded-phase SI particles and, more recently, of pure polymeric resins of appropriate particle size, SPE is becoming the preferred method for isolation of organic components from predominantly aqueous samples.

Disposable cartridges filled with sorbents of a small particle size are employed, and the sample and the different mobile phases are flushed with a syringe as a low-pressure pump. The clean-up principles are similar to other open-column techniques. This method is quick and simple to operate, most sample handling losses are avoided and it is easily automated and coupled to LC.[2,3] LC has probably emerged as the method of choice in the pharmaceutical

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

field. Gas chromatography (GC) has gained more prominence for drug screening and coupled with mass spectrometry (MS) for confirmation analysis too.

In recent years, an increasing number of LC methods incorporating on-line sample clean-up by SPE on disposable precolumns by use of column switching have been developed. Switching devices permit the off-line multistep methods to be transformed into single-step procedures by the on-line purification of the sample. The on-line coupling of SPE and capillary GC still poses a number of problems.[4]

A topic close to pharmaceutical analysis is *residue analysis*, as the determination of antibiotic residues in food products of animal origin. SPE on disposable cartridges or precolumns has also been proposed as a substitute for or combined with LLE[5] in this field.

In systematic *toxicological analysis* the substances present are not known at the start of the analysis. In such an undirected search the extraction procedure must be a general procedure where a compromise must be reached in that the substances of interest are isolated at a yield as high as possible and the interfering substances from the biological material are removed.[6] For a long time the traditional sample work-up technique in analytical toxicology was LLE, often combined with sample pretreatment procedures such as conjugate hydrolysis, digestion and protein removal. Although LLE proved to be suitable in a substantial number of cases, the disadvantages of this technique, for example matrix interferences, emulsion formation, use of large volumes of hazardous solvents, have troubled the analyst. The SPE approach can partially overcome the drawbacks of LLE.

In recent years the development of suitable materials for SPE and an increasing demand for on-line sample treatment procedures have provided a new impetus to extraction approaches.

2 BASIC THEORY

This section briefly summarizes the most used sorbents and methods in SPE. The same analyte/sorbent interactions that are exploited in high-performance liquid chromatography (HPLC) are used in SPE. Ion exchangers have been also included due to their use in sample pretreatment processes and because the process involved in the separation is a physico-chemical process, as in the sorption.

2.1 Sorbents and Interaction Mechanisms

The first sorbent used for SPE was XAD™ resin as mentioned above. This resin is a low-polarity styrene–divinylbenzene copolymer which possesses the macroreticular characteristics essential for high sorptive capacity. In addition to polymeric resins, the solid-phase sorbents available include common inorganic sorbents (SI, alumina, Florisil™), siloxane-bonded SI materials (octadecyl, octyl, ethyl, cyclohexyl (CH), phenyl (PH), 3-cyanopropyl (CN), diol (2OH), 3-aminopropyl (NH_2), etc.), ion-exchange macroreticular resins, and specialty products such as resin-bonded phenylboronic acid (PBA) and activated carbon. Chemically bonded SI, usually with a C_{18} or C_8 organic group, is by far the most commonly used material for SPE. At present, cross-linked polystyrene and other porous polymeric resins[7] and mixed-mode SPE sorbents[8] are finding increasing use.

The packing material with particle sizes in the range of 30–60 μm is sandwiched between two porous frits with a pore diameter of about 20 μm in a column. The bottom end of most cartridges is terminated in a leur lok fitting. The cartridges are available in several sizes containing from 50 mg to 10 g of sorbent, with the 100–500 mg sorbent cartridges being the most used in the pharmaceutical field. Approximate values for the capacity and bed volume of the columns are 5% sorbent mass or 0.4–0.6 mequiv mL^{-1} for ion-exchange sorbents and 120 μL per 100 mg of sorbent, respectively.

A more recent approach to SPE is the use of a membrane (0.5 mm thick, 25 or 47 mm in diameter) loaded with an appropriate solid material immobilized within a stable, inert matrix of fibrillated poly(tetrafluoroethylene) (PTFE). These membranes are 90% by weight particle-loaded and 10% PTFE with very dense packing of the sorbent of a smaller average particle size (8 μm) than used in the conventional SPE cartridges. The capacity of the membranes is similar to that of the cartridges, but the small bed volume allows for reduced elution volumes, resulting in more concentrated eluates. Particle-loaded membranes are supplied in disk format for large-volume use and are contained in disposable cartridges for the small volumes appropriate for pharmaceutical analysis.

For the on-line mode, the majority of the applications use particle sizes in the 10–40 μm range. The internal diameters of both the sample clean-up column and analytical column should be the same, in order to minimize extracolumn band broadening. The vast majority of studies employ an internal diameter in the 2–4.6 mm range. Short precolumns (between 5 and 10 mm) are preferable because the duration of the flushing needed to remove undesirable matrix compounds is minimized. Packed precolumns are commercially available from several manufacturers, but manual slurry or dry packing of a precolumn does not present any real problems and, in addition to rapid exchange, allows the easy screening of new packing materials.

Table 1 Sorbents and interaction mechanisms in SPE

Interaction	Sorbent	Chromatographic mode	Analyte functional groups	Matrix
	SI-based bonded phase			
Hydrophobic	C_{18}	Reversed-phase	Aromatic rings	Aqueous
Nonpolar–nonpolar	C_8		Alkyl chains	
Van der Waals forces	C_2			
	CH			
	PH			
Hydrophilic				
Polar–polar	CN	Normal-phase	Hydroxyls	Nonpolar
Hydrogen bridges	2OH		Amines	
$\pi-\pi$ bond	NH_2		Heteroatoms (S, O, N)	
Dipole–dipole				
Induced dipole–dipole				
Ion-exchange	SXC	Ion-exchange	Amines	Aqueous
	PRS		Pyrimidines	
	CBA			
	SAX		CBAs	
	PSA		Sulfonic acids	
	NH_2		Phosphates	
	DEA			
Multiple				
Hydrophobic/ion-exchange	Mixed bonded SI	Reversed-phase and Ion-exchange	Acidic, neutral, and basic compounds	Aqueous
	No bonded phase			
Hydrophilic/hydrophobic	SI	Normal-phase	Generally used to provide class separation by dividing the sample into fractions containing a similar number and type of functional groups	Nonpolar
	Alumina			
	Florisil™			
	Diatomaceous earth			
	Activated carbon			
Hydrophobic/hydrophilic	Copolymer resins	Reversed-phase	Aromatic rings Alkyl chains	Aqueous
Covalent	PBA	Reversed-phase	Nucleotides, nucleosides Carbohydrates Catecholamines	Aqueous

C_{18}, octadecyl; C_8, octyl; C_2, ethyl; SXC, benzenesulfonic acid; PRS, propylsulfonic acid; CBA, carboxylic acid; SAX, quaternary amine; PSA, primary/secondary amine; DEA, diethylaminopropyl.

There are three general extraction mechanisms used in SPE: polar, nonpolar and ion-exchange. The main retention mechanisms for the most used sorbents are shown in Table 1.

Although the same type of SPE material can be obtained from different manufacturers, the results using SPE material from different manufacturers, and even results obtained from different batches from the same manufacturer, may show significant differences in behavior, i.e. in particle size distribution and flow velocities.

2.2 Method Development

It is recommended to find the sorbent that will provide the best results. For that, the potential interactive properties of the isolate(s) and matrix, taking note of functional groups, should be considered (Table 1). Also other known influences that may affect the extraction negatively are important, such as protein binding, properties of the isolate(s) like stability, solubility and pK_a.

If the analyte(s) has nonpolar (alkyl chains, aromatic rings), polar (hydroxyls, amines, keto groups), or ionic (amines, CBAs) functional groups then these properties can be selectively employed to facilitate retention. The undesired constituents of the matrix may interfere with retention of the analytes, requiring consideration of a different mechanism.

The same operational modes as in HPLC are used in SPE. Table 1 shows the option generally chosen for each sorbent.

The sample processing involves four distinct steps. Pretreatment of the sorbent with an activating solvent (such as methanol for chemically bonded SI and porous polystyrene resins) must be carried out to obtain better surface contact and to remove impurities from the sorbent. It is returned to the ready condition by washing

with three or four bed volumes of a solvent as similar to the sample solvent in polarity, ionic strength, and pH as possible. The sample is then sorbed onto the cartridge. The maximum volume that can be sampled depends on the breakthrough volume for the analyte(s). The cartridge is then rinsed with a weak solvent to remove undesirable matrix components. In the final step the analytes are eluted by a solvent of sufficient strength to desorb the analytes in a small volume without displacing more strongly sorbed matrix components.

The typical solvents used for nonpolar extraction are methanol, acetonitrile, ethyl acetate, chloroform, acidic methanol and hexane. Methanol, isopropanol, and acetone are used for polar extraction. Alkaline and acidic buffers and high ionic strength solutions are employed for ion-exchange extraction. Acidic buffer and acidic methanol are the solvents selected for covalent extraction.

The sample and solvents are flushed into the cartridge manually by use of a syringe, by centrifugation or in a vacuum manifold that permits the processing of between 10 and 24 columns at one time generally. SPE membranes require a filtration manifold or special apparatus for multiple extraction of several disks. For the on-line option, switching valves and pumping systems are necessary.

Different strategies exist to improve the sample clean-up by SPE, taking into consideration the sorbent used. Table 2 summarizes these strategies.

Table 2 Strategies for improving sample clean-up by SPE

Problem	Sorbent	Strategies
Inadequate analyte retention	Polar	Change to more nonpolar solvent
	Nonpolar	Change to more polar solvent
		Ionic strength ≤ 0.1
		Bad activation
		Ionic analyte
	Ion-exchanger	Dilution
		Change the pH
		Decrease the ionic strength
Inadequate elution	Polar	Study the secondary mechanism
	Nonpolar	Modify the ionic strength
		Increase the nonpolar solvent
	Ion-exchanger	Increase the elution volume
Poor sample clean-up	Polar, nonpolar, ion-exchanger	Increase the strength of the matrix washing solvent
Poor reproducibility	Polar, nonpolar, ion-exchanger	Protein binding
		Analyte absorption on the sorbent pH

3 OFF-LINE VERSUS ON-LINE PROCEDURES

Off-line SPE may be converted into an on-line procedure using column switching techniques. Its use in HPLC was first reported in 1973.[9] The term ''column-switching'' or ''coupled column chromatography'' includes, in the widest sense, all techniques by which the direction of the flow of the mobile phase is changed by valves, so the effluent from a primary column is passed to a secondary column for a defined period of time. Switching can be effected manually or by automated controllers.

Coupling LC/LC is a well-established technique for sample clean-up in the analysis of pharmaceutical samples. Its success depends on the type of sample, the precolumn, the eluent and the column-switching configuration.[2] The only significant difference with the off-line SPE is the switching network.

In the simplest configuration, only a switching valve is required in addition to a basic chromatograph. It should be indicated that during the sampling and clean-up steps, the eluent in the analytical column is stagnant. Therefore, this configuration may lead to considerable baseline fluctuations depending on the elution conditions, which limits its applicability. More powerful systems can be achieved at a reasonable cost by using an additional pumping system. In such a way, the analytical column is equilibrated during the clean-up stage, and only the fraction of eluent containing the compounds of interest is transferred to the analytical column (Figure 1).

In spite of the level of instrumentation, different transfer modes can be used. In forward flush (also called straight flush) configurations the flow direction in the precolumn is not changed during the transfer stage, which prevents solid particles retained at the head of the precolumn from being sent to the second column. However, for samples containing compounds which are strongly retained in the precolumn, backflush configurations (in which the flow direction of the mobile phase through the precolumn is reversed for the transfer onto the secondary column) are preferable, because the

Figure 1 Typical scheme of a column switching system used for on-line SPE.

desorption of the most retained components after every injection is easier.

In order to improve sample clean-up, several columns can be coupled easily in the on-line mode by using several switching valves. In linear coupled-column systems, the peak capacities of the individual columns are summed. A review of commonly used switching networks is given by Ramsteiner.[10]

One of the most obvious trends in analytical laboratories is the growing need for automation. SPE has been traditionally performed in non- (or semi)automated mode. However, an important reason for growth is that SPE is amenable to automation, and today there are several examples of commercially available systems for automated off-line and on-line SPE.

Compared with manual SPE, automated SPE also improves the reproducibility because variations in experimental parameters are reduced or even eliminated. Another important advantage of automated SPE in pharmaceutical analysis is safety, because workers are protected from toxic substances and from samples obtained from patients with a range of diseases (HIV or hepatitis B, for instance).

There are different approaches to automation of SPE, which involve different levels of apparatus cost. These approaches can be categorized into off-line and on-line systems.[11]

3.1 Off-line Automated Solid-phase Extraction

In off-line methods the SPE cartridges are not directly connected to instrument, normally a liquid or a gas chromatograph. Unattended sample work-up and analysis can be performed as a result.

The simplest approach to automation is based on the employment of liquid-handling devices which include SPE in their functions. These workstations usually incorporate precision pumps (which deliver measured volumes of liquid to test tubes) with multisolvent capabilities, replaceable pipettes, and random access to vessels. The system also includes a SPE rack, with the cartridges or disks, and a liquid-handling probe. The probe runs in the trays (usually x–y–z), so it can reach any of the positions: samples, tubes or SPE cartridges, manipulating the sample and providing air or nitrogen (to move liquids through the cartridges) and the extraction or washing solvents. Specially designed probes or column caps create a tight seal in the cartridges. The syringe pump delivers conditioning solvents, which are then pushed through the cartridges by means of the pressurization line. Next, the sample is added and the pressurization step is repeated. If required, one or more washing solvents are also added, and pressure is again applied. Finally, the cartridge (which is over the waste container) is moved, so the sample is eluted into a clear container for further processing. Optional equipment such as a bar-code reader is also available in many commercial systems. All operations are controlled by a keypad controller or by a computer. In semiautomated systems, the extracts collected are manually injected onto the chromatograph. However, total automation is possible by connecting the workstation to the analytical column, for instance by means of a loop injector. Examples of this approach to automation are the Gilson ASPEC™ or the Hamilton Microlab SPE systems.

A more sophisticated form of SPE automation is that using flexible or semiflexible robotic manipulation. Semiflexible systems incorporate a robot-like device which performs only a few of the steps involved in sample preparation. Some modern chromatography autosamplers fit into this category. These devices extend the possibilities of unattended sample work-up because operations typically involved in sample conditioning (internal standard addition, dilution, digestion or derivatization) can be also performed in a fully automated way. The Prep-Station (Hewlett Packard) system is a typical example of this kind of instrument.

In flexible systems, the robot can be programmed to perform all operations involved in the sample conditioning procedure: weighting, dilution, and of course, those required in SPE. Nevertheless, robots are too expensive to be used in SPE operations. For this reason, in normal applications the robot is interfaced to a SPE work-station. The robot may move cartridges from a dispenser to racks holders, remove spent cartridges or transfer collection tubes, but rarely does the robot wait for liquids to be dispensed or for air to pass through the cartridges; instead, the SPE workstation performs these operations. Robots compatible with SPE have been commercialized by different companies such as Zymark Corporation or Hewlett Packard, among others.

3.2 On-line Automated Solid-phase Extraction

In on-line systems, the SPE device is inserted into the liquid or gas stream of the chromatograph, which means that it becomes part of the chromatograph. Automated sample preparation with on-line SPE is accomplished by using column-switching. When the precolumn is loaded with the sample (normally a biofluid), the analytes are selectively retained. The precolumn is then washed to remove endogenous interferents, so that they are sent to waste. The analytes are finally desorbed and transferred by means of an electronically controlled switching valve, which passes the mobile phase through the precolumn, and the drug is eluted out to the analytical LC or GC column. In such a way, off-line sample manipulation is reduced to a minimum and the entire analysis can be

easily automated. Hence, SPE/LC or SPE/GC can be considered particular forms of multidimensional LC/LC and LC/GC chromatography respectively.

The SPE/LC approach is particularly well suited for pharmaceutical analysis, as a vast majority of the samples of interest are compatible with liquid chromatographic systems (especially those operating under reversed-phase conditions). Besides the inherent advantages of automation, this methodology offers some advantages over off-line automated systems, for example, protection of light-sensitive or oxidation-sensitive analytes, because during sample processing they are kept away from light and air respectively. Moreover, implementation is relatively inexpensive compared with off-line SPE devices. In many applications, the cost is little more than a switching valve and a precolumn unit over the chromatograph needed for a manual method. However, an additional pump may sometimes be necessary for washing the precolumn. Although good stability is normally achieved for the repetitive injection of 10–100 μL of untreated samples, a clear disadvantage is that periodic regeneration or replacement of the precolumn may be needed to prevent clogging, especially when processing biofluids with a large amount of proteins (for example blood or plasma). Some commercial systems incorporate cartridge holders that can be loaded with several cartridges. The individual cartridges (which act as a precolumn) are connected to the analytical column by means of a switching arrangement. Each cartridge is periodically replaced by a fresh one, so clogging or memory effects are minimized. Alternatively, SPE in the individual cartridges is performed off-line, and then the cartridges are automatically inserted into the flow stream. Examples of this type of device are the AASP (Varian) and Prospect (Spark Holland) systems.

Whereas on-line SPE/GC is quite popular in environmental analysis, its use is not widespread in the pharmaceutical field. This can be explained by the successful performance of SPE/LC methods, and also by the inherent difficulties of coupling SPE to GC, with either solvent or thermal desorption. Moreover, in pharmaceutical analysis care must be taken to prevent water-containing eluents from being transferred to the GC part of the system. This problem may be overcome by drying the cartridge with an inner gas stream before the transfer step. Another possibility is to place a drying cartridge between the SPE precolumn and the GC system. Nevertheless, with modern equipment the introduction of up to 100 μL of solvent can be achieved.

A precolumn can also be used to couple a SPE workstation to a GC chromatograph, as illustrated in Figure 1. Larger sample volumes (up to several milliliters) can be processed in the SPE cartridges. The analytes are subsequently reconcentrated in the precolumn, which facilitates the complete transfer of the relevant fraction of solvent to the GC system. A proper selection of the precolumn packing would also improve the selectivity, for example by using a packing material with retention capabilities different to those of the SPE cartridges. If required, the precolumn can be dried before connection to the GC unit. As a result, excellent sensitivity and selectivity can be achieved. For example, the system described in Figure 2 enables the detection of some benzodiazepines at low parts per billion levels from only 1 mL of plasma.[12] Similarly, a precolumn can be used to couple a dialyzer module to a GC chromatograph (also to a LC chromatograph). The dialysis step adds selectivity as sample macromolecules do not reach the SPE unit.

A very interesting alternative for on-line automated systems with GC and HPLC is solid-phase microextraction (SPME), because difficulties derived from the injection of large volumes of solvents can be overcome. Automated SPME has been achieved by using polymer-coated fused-SI fibers. The fiber previously fixed to a microliter syringe is automatically inserted into the sample vial. The analytes diffuse and partition in the polymeric phase. Next, the fiber is removed from the vial, and the analytes are thermally desorbed, on-column, in the injector of the gas chromatograph. For HPLC an interface consisting of a six-port switching valve and a desorption camera are needed. This interface replaces the injection circuit of the liquid chromatograph.

4 PHARMACEUTICAL ANALYSIS

4.1 Quality Control

The control of pharmaceutical quality is one of the primary objectives of drug manufacturers. Quality control (QC) has been defined as actions such as testing, monitoring and inspecting taken to detect and control defects. The control of drug substances and drug product quality involves developing sets of tests and specifications for raw materials, intermediates of interest and final products, performing the tests on the subject material, compiling the results and submitting them to regulatory authorities on a regular basis. From the synthesis of a drug onwards, its identity, strength, purity and quality are continuously assessed and monitored.

The British and USA pharmacopoeias recommend microbial assay, ultraviolet (UV) spectrophotometric and HPLC methods for the determination of pharmaceutical preparations. HPLC is currently probably the most popular for impurity and dissolution testing and formulation determination. However, very few publications exist on QC applications of LC other than several examples that

list QC or quality assurance in their titles as part of a method development study.

In the development of new drugs the determination of the purity is important in order to establish the acceptability of batches for safety assessment and clinical trials. In general, process impurities include trace substances resulting from the drug substance synthesis, and trace side-reaction products or contaminants not removed by the isolation and purification scheme. Regulatory authorities set various levels for individual and total impurities in both drug substance and drug product that must be reported and investigated. Ideally, the total amount of impurity, as well as the quantity of each individual impurity, should be monitored in the bulk drug. Prabhu et al.[13] described the isolation and concentration of impurities in 3-[2-(2-benzoxazolyl)ethyl]-5-ethyl-6-methyl-2(1H)-pyridone (L-696229) using sequential preparative HPLC, SPE, and LLE. Three SPE cartridges connected in series were used.

An example of the use of SFE in studies related to dissolution testing can be found in Kenney et al.[14] The antiarrhythmic drug L-768673 in pharmaceutical preparations was retained on a C_{18} SPE column and was analysed by HPLC and UV detection at 245 nm.

We have proposed spectrophotometric procedures that integrate sample clean-up and derivatization in the same process by using C_{18} solid supports. The potential of this technique was evaluated determining the content of DL-amphetamine sulfate in centramine tablets using 1,2-naphthoquinone-4-sulfonic acid (NQS).[15] This methodology has been also used for the determination of cephalexin in capsules and oral suspension (both singly and in combination with bromhexine).[16]

While development of racemic drugs is still permitted, examples are known in which enantiomeric pairs both have the same or different biological activity or in which one member is active and the opposite isomer is completely inactive. Enantiomeric purity is controlled in drug manufacture, storage and shipment for both bulk drug and product for molecular entities with chiral centers. The specific chiral LC methods have involved three general techniques, namely precolumn derivatization to yield diastereomers, mobile phases with constituents to afford separation of enantiomer pairs, and chiral stationary phases. Lots of references can be found on these techniques and several reviews have been written.[3,17,18] We have used the first option for chiral analysis of amphetamine in pharmaceutical samples using a mixture of *o*-phthaldialdehyde and *N*-acetyl-L-cysteine as derivatizing reagent.[19] The assay uses a 20 mm × 2.1 mm inner diameter precolumn packed with a Hypersil™ C_{18} (30 μm) material for purification and derivatization. The resulting derivatives were subsequently separated in a C_{18} achiral column using a mobile phase of acetonitrile–methanol–acetate buffer and detected by fluorescence.

4.2 Drug Monitoring

The analysis of drugs in a biofluid matrix by HPLC or any other separation–detection scheme is usually difficult owing to the large number of substances present in the sample and because the compounds of interest are often present at very low concentration. The most problematic fluids are those that contain a large fraction of proteins: blood, plasma, and serum. Cerebrospinal and interstitial fluids, as well as urine, are generally more compatible with LC, owing to their low protein content. Solid samples can be processed after solubilization and homogenization.

Many methods have been published for the determination of drugs in biological matrices using SFE cartridges for sample clean-up. Table 3 shows representative examples using different sorbents for screening analysis and determination of several drugs. For each analysis Table 3 also gives the separation and detection techniques employed. Several kinds of drugs have been included, such as anticonvulsants, anti-asthmatics, antiarrhythmics, antibiotics, diuretics and illicits. Although the most used detector in HPLC is the UV/visible detector, examples of other detectors are shown in Table 3. Some reports with GC are also recommended. As an example of an analysis that needs a derivatization step, amphetamine and methamphetamine determination has been included in Table 3. SPE has been proposed for both reversed-phase HPLC and normal-phase HPLC. An overview of screening procedures using diatomaceous earth, polystyrene–divinylbenzene copolymers and mixed-mode bonded SI sorbents can be found in Franke and de Zeeuw.[6]

As mentioned earlier, the use of column-switching techniques has become an area of major interest. Its application to drugs in biological samples by HPLC methods incorporating on-line sample clean-up by SPE using column-switching has been reviewed.[2] The time required for the sample clean-up process using this technique is drastically reduced, as minimum off-line sample manipulation is involved. Therefore, this technique can be very useful where a large series of samples must be processed. As a result, the precision is generally improved. Some examples of that improvement in the analytical results are given in papers about on-line sample clean-up with an octadecylsilica-C_{18} SPE precolumn and using column-switching for screening of diuretics and probenecid[38,39] and the determinations of acetazolamide[40] and triamterene[41] in urine samples using an octadecylsilica-C_{18} SPE precolumn.

Antibiotics are used in food-producing animals not only for treatment of disease, but also to maintain health and

Table 3 Representative examples of the use of SPE cartridges for sample clean-up in drug monitoring

Analyte	Studied sorbent	Matrix	Separation and detection techniques	Reference
Screening of amiloride, acetazolamide, hydrochlorothiazide, triamterene, chlorthalidone, furosemide, cyclothiazide, bendroflumethiazide, bumetanide, ethacrynic acid, probenecid and spironolactone	C_{18}, C_8, C_2, CH, PH and cyano	Urine	HPLC with photodiode array	Campíns-Falcó et al.[20,21]

promote growth. The use of unauthorized antibiotics or the failure to follow label directions for approved antibiotics could result in unsafe antibiotic residues in food products. Therefore, monitoring antibiotic residues in food forms part of a general policy to prevent unapproved uses of antibiotics. A review of the developments in LC methods of analysis for antibiotics (including aminoglycosides, chloramphenicol, sulfonamides, tetracyclines, macrolides and β-lactams) has been published.[5] This paper also covers clean-up procedures such as SPE.

5 COMPARISON WITH LIQUID–LIQUID EXTRACTION

LLE has been the most used technique for sample clean-up, but SPE is now becoming the preferred method for this step of the analysis. This section focuses mainly on a comparison of the two methods.

5.1 Instrumentation

The equipment involved in using a sorption column for off-line processing can be very simple for manual use as described in earlier sections. For automated off-line SPE more sophisticated apparatus is required. On-line assemblies require only a switching valve for the simplest configuration, and additional pumps and valves for specific applications. In summary, SPE can work with or without expensive apparatus and the partial or total automation of the on-line mode is relatively easy.

In the simplest form of LLE a separatory funnel is needed. When the distribution constant of the solutes are very small, continuous extractors or countercurrent distribution apparatus is required. A continuous liquid–liquid extractor can be coupled to a gas or liquid chromatograph in three different ways: indirectly, by collecting the flow of the phase of interest in vials after the sample has been aspirated or injected into a flow injection manifold and subsequently injecting their contents manually into the chromatograph; on-line, via a simple turntable acting as an interface between the two continuous separation systems; and on-line, but directly, with no interface or discontinuity between the extractor and the chromatograph. Simplicity and the degree of automation of these three alternatives increase in the same order as they have been mentioned. In all cases SFE is generally easier and cheaper than LLE.

5.2 Recovery and Precision

Disadvantages of LLE are matrix interferences, emulsion formation, and the use of large volumes of hazardous solvents. SPE can overcome these drawbacks. The methods used for breaking an emulsion in LLE are generally time-consuming. The most common method is the addition of salt (e.g. NaCl) either as a solid or a saturated aqueous solution. Settling of the lower phase can be accelerated in a separatory funnel by the application of heat, as with an infrared lamp. More difficult emulsions may require high-speed centrifugation to separate two phases. Another technique is the use of low-melting-point organic solvents, such as ether, for the extraction of aqueous samples. Emulsions in this case are first separated by centrifugation, then the mixture is frozen in dry ice or liquid nitrogen. Finally, the organic phase is simply poured off leaving the frozen aqueous phase behind. Another option is to use filter papers.

Where extraction gives low recovery of the desired simple components despite optimum adjustment of solvent polarity and pH, recovery can be increased by using large volumes of solvent for the same sample quantity, and by using successive or continuous extraction. Following LLE of the sample, the solvent phase is normally filtered and may be further dried over anhydrous sodium sulfate, concentrated by evaporation and subjected to further clean-up procedures. The rate and extent of extraction may be different for a solute in a test system and in the presence of a sample matrix. Partial association of drug substances with proteins in plasma samples has been recognized.

Diuretics can provide a good example for testing the recoveries obtained for acidic, basic and neutral drugs in urine samples processed by LLE and off-line and on-line SI-based bonded-phase SPE. Table 4 shows results obtained in our research group.[20,21,38,39] As can be seen in Table 4, the acidic diuretics present better recoveries by LLE in acidic conditions, while basic diuretics increase their recoveries in basic conditions. Neutral diuretics present similar values for both acidic and basic extractions. The urine blanks obtained by SPE in different SI-based bonded-phase cartridges are similar to those obtained by LLE in acidic conditions (Figure 3). The standard deviations obtained are similar to those obtained by LLE, but the recoveries achieved are better, although only a unique cartridge has been used for sample clean-up. C_{18} sorbent provides higher recoveries for all the analytes. The washing solvent used for clean-up of the matrix was water. The results obtained with 2 mL and 0.5 mL of water are shown in Table 4. The smaller amount of water (0.5 mL) should be only used if acetazolamine is the compound being analyzed.

The efficiency of the on-line method is similar to that found with the C_{18} cartridges (Figure 3 and Table 4). The recoveries obtained for standards and spiked urine are the same, indicating that the sample matrix does not affect the recoveries of diuretics and probenecid. The precision is excellent with coefficients of variation below 6% in spiked urine samples. Also, it is greatly improved

Table 4 Comparative study of LLE and off-line and on-line SPE for diuretics

in comparison to LLE or SPE on disposable cartridges, as no on-line operation is involved.

Styrene-divinylbenzene (SDB) resins are especially interesting for analysing urine samples, since sulfate and glucoronide conjugates can be isolated. Extraction yields are in the order of 80%, with a precision of 7–27%, which are on average rather high.[6] These types of compounds are not amenable for classic solvent extraction. The SDB resin is also used for isolating substances from other biological matrices such as blood, serum, bile, gastric content, and tissues.

The extraction yields of substances isolated from different biological samples may vary considerably, however. The resin has to be cleaned very carefully. Recently, new SDB-based SPE columns (e.g. Bond Elut ENV, Varian) have become available, which overcome the above drawbacks. Moreover, SDB material in extraction disks can minimize volumes of elution solvents while still allowing relatively large sample volumes; this is a main characteristic of the SDB sorbents. Screening methods for acidic, basic and neutral compounds using this type of material are not yet available.

6 OTHER APPLICATIONS OF SOLID-PHASE EXTRACTION

6.1 Concentration

In pharmaceutical testing (stability or dissolution tests, for example) high concentrations of analytes are usually involved. Consequently, dilution of the samples is often necessary prior to the actual measurement. In contrast, many other applications usually require some form of analyte enrichment: identification and/or quantification of drug impurities in pharmaceutical preparations (by-products from the synthesis or degradates); pharmacokinetic studies; therapeutic drug monitoring; and in those situations where the sample volume is restricted, particularly if the sample has to be divided between several screening tests. It should be noted that, in a majority of such cases, the analytes also require purification owing to the large number of substances present in the samples.

Analyte enrichment with SPE column or disk cartridges is based on collecting the analytes in a volume of solvent

Figure 3 Typical chromatograms obtained at 230 nm from a urine sample by (a) acidic LLE, (b) basic LLE, (c) off-line SPE into a C_{18} column cartridge and (d) on-line SPE with column switching using a precolumn packed with a C_{18} packing.

lower than that of the sample. Unfortunately, in this process, undesirable matrix components may also be concentrated, especially if low selective packings (such as common reversed-phase materials) are used for retention of the compounds of interest. For this reason, washing of the cartridges with an appropriate solvent or mixture of solvents is often needed to improve the selectivity.

In principle, the enrichment factor is only limited by the losses of the analytes from the cartridges due to breakthrough during both the sampling and the washing steps. Therefore, the success of the enrichment procedure depends on a variety of factors: sample volume and type; characteristics of the cartridge; nature and volume of the washing eluent; and volume of solvent used to collect the analytes.

In order to achieve maximum enrichment, a careful selection of the SPE cartridges should be made according to the basic principles indicated in previous sections. The main parameters to be considered are type of packing material, particle size and loading capacity. Cartridges packed with 100 mg of packing material are generally suitable for most applications involving the analysis of up to 1 mL of the most common biofluids. In many instances, apolar packings (C_{18} or C_8) provide nearly quantitative recoveries of the analytes and the required selectivity, as salts and other very polar matrix constituents are wasted out with a relatively small volume of washing solvent (normally water or a buffer). However, more selective packings (protein-coated phases or immobilized antibodies) may be required for some applications.

For a given SPE cartridge, the volume of washing solvent should be as low as possible in order to prevent breakthrough. Therefore, the use of large volumes of samples may not compensate the losses of interesting compounds during the washing stage. With respect to the sample type, the most problematic fluids are those containing a high content of particulate material. In those cases, the employment of large sample volumes may be limited by the low flow rates attainable not only during the sample loading but also during the washing and desorption steps. This effect can be minimized if the samples are previously filtered or centrifuged to prevent blocking of the cartridge frits.

However, in order to achieve the maximum enrichment factor, the volume of solvent used to collect the analytes should be as low as possible. This volume is mainly determined by the amount of packing material in the cartridge, provided that a strongly eluotropic solvent is used for desorption. Cartridges containing 100–200 mg of packing permit the collection of the analyte in relatively small volumes, typically a few hundred microliters. Lower volumes lead to unsatisfactory reproducibility because, after the desorption step, small (and variable) fractions of the eluent may remain in the cartridges. As in LLE, the enrichment factor can be improved by evaporating the collected extracts to dryness, followed by redissolution. Evaporation, however, is time-consuming and may be inadequate if volatile compounds are going to be analyzed. It should be noted that, if chromatography is the final step of the analysis, the sensitivity attainable with the SPE column or with disk cartridges is limited by the fact that only a fraction of the collected extracts is finally injected into the chromatograph.

On-line SPE is an attractive alternative for enrichment of the analytes in chromatography (especially in LC).[2] In this approach enrichment is based on retention of the analytes in a precolumn when a large volume of sample is flushed through it; the precolumn is then flushed with an appropriate solvent, and the enriched analytes are finally transferred to the analytical column.

The main problems associated with the direct injection of biofluids in chromatographic systems are precolumn clogging and irreversible adsorption of matrix constituents to the stationary phases. For these reasons, the volume of samples that can be processed with on-line SPE are significantly lower than those that can be handled with SPE cartridges. Otherwise, rapid pressure development occurs, and the performance of both the precolumn and the analytical column may seriously deteriorate after a few injections. Although special packings (such as restricted access materials) have been designed for the on-line SPE in the biomedical field,[42] sample volumes of 50–100 μL can be adequately processed with conventional packings. Nevertheless, the sensitivity attainable with on-line SPE is similar to that of the off-line methods, as in the latter approach only a fraction of analyte is introduced in the chromatographic system. For this reason, on-line SPE is the best alternative for trace enrichment when the sample volume is restricted.

Moreover, careful selection of working conditions allows the injection of large sample volumes with suitable stability for most applications. For example, a straight-flush configuration (in which the flow direction of the mobile phase through the precolumn is not changed for the transfer onto the analytical column during the transfer step) protects the analytical column from solid particles or matrix components retained at the head of the precolumn, thus making possible the injection of relatively large volumes of biofluids. In addition, the precolumn lifetime can be extended by including a regeneration step in the final procedure. For regeneration, the precolumn is disconnected from the analytical column, and then it is flushed with a strongly eluotropic solvent. Since regeneration can be carried out during the chromatographic separation, the total analysis time is not increased. In many instances, occasional cleaning (e.g. when daily work is finished) allows the analysis of several samples with suitable stability and performance of the system for routine work. This is illustrated in Figure 4, which shows the effect of the successive injection of 250 μL of untreated plasma on back-pressure. Although back-pressure in the precolumn (packed with a 40-μm

Figure 4 Effect of the number of injections on the back-pressure of the precolumn (+), the analytical column (×), and on the two columns linked (●). The dashed line indicates cleaning both columns with acetonitrile (approximately 15 mL).

C_{18} stationary phase) is approximately duplicated every 25 injections, the pressure at the top of the analytical column remains constant. Cleaning of the precolumn with an organic solvent (e.g. acetonitrile) every 25 injections reduces pressure and permits the system to be used for the analysis of many other samples. Under these conditions, quantification at sub parts per million levels is possible for a large number of compounds in plasma or urine.

Enrichment via a precolumn can also be used to overcome dilution, if dialysis is used to remove macromolecular constituents in biofluids (see section 3.2).

6.2 Derivatization

In pharmaceutical analysis, chemical derivatization is often needed to enhance the sensitivity and/or the selectivity of the overall analytical process, particularly when using LC. In this respect, most of the described procedures are based on precolumn solution derivatization because these reactions do not suffer from kinetic limitations and can be conducted under very flexible conditions (pH, temperature). In the analysis of biological samples, a preliminary step is analyte purification because the reagent can be reactive toward matrix constituents. In addition, derivatization generally involves extra sample handling aimed at removing unreacted reagent or to preconcentrate the derivatives. As a result, the final procedure may be very tedious and time-consuming.

Precolumn derivatization may be simplified in some instances with SPE materials. Krull et al.[43] proposed a very interesting approach based on using solid-phase reagents for simultaneous clean-up and derivatization. The solid-phase reagent contains ionic or covalent labile tags that possess specific detector enhancement properties. The choice of the pore size of the solid support (or the percentage of cross-linking when using a polymer network) permits size exclusion, thus enabling retention of small molecules but hindering the large ones. After purification, the adsorbed analytes are made to react with the reactive part of the solid-phase material. Finally, the derivatives formed are desorbed for further analysis. This methodology has been successfully used for the derivatization of several amines with a variety of reagents in both off-line and on-line modes.

Another approach to derivatization with SPE supports is based on the successive addition of the SPE material (normally a resin) and the derivatization reagent to the samples. The derivatives are retained on the SPE material, and isolated from the matrix and from the excess of reagent by filtration. Next, the derivatives are desorbed from the resin, which is then separated by filtration. This methodology has been applied, for example, to simplify multiple derivatization required for the analysis of prostaglandins in plasma by GC.[46]

Alternatively, derivatization can be carried out in conventional SPE cartridges or precolumns (in on-line SPE) as has been developed in our group. In the former approach, the SPE cartridge is used to selectively retain and/or preconcentrate the analytes, and then to retain the derivatives formed when an aliquot of the reagent is flushed though it. The analyte and the reagent are made to react for a given period of time. Then, the excess of reagent can be removed (if

required) by flushing the cartridge with an appropriate solvent. Finally, the derivatives are collected for further processing. The on-line methodology is based on similar principles, but the time of reaction is controlled by stopping the flow rate in the precolumn after injecting the reagent. It is important to note that, under this approach, sample clean-up, enrichment and derivatization can be performed without manual intervention. In addition, minimum instrumentation is needed over conventional equipments: an isocratic pump, a precolumn and a switching valve. This methodology has been applied to the LC determination of different types of compounds such as amino acids, amphetamines, and polyamines in plasma and urine, in combination with reagents typically used to improve UV or fluorescence detection, as can be seen in Table 5.

ABBREVIATIONS AND ACRONYMS

CBA	Carboxylic Acid
CH	Cyclohexyl
CN	Cyanopropyl
DEA	Diethylaminopropyl
GC	Gas Chromatography
HPLC	High-performance Liquid Chromatography
LC	Liquid Chromatography
LLE	Liquid–Liquid Extraction
MS	Mass Spectrometry
NH_2	Aminopropyl
NQS	1,2-Naphthoquinone-4-sulfonic Acid
PBA	Phenylboronic acid
PH	Phenyl
PRS	Propylsulfonic Acid
PSA	Primary/Secondary Amine
PTFE	Poly(tetrafluoroethylene)
QC	Quality Control
SAX	Quaternary Amine
SDB	Styrene-divinylbenzene
SI	Silica
SPE	Solid-phase Extraction
SPME	Solid-phase Microextraction
SXC	Benzenesulfonic Acid
UV	Ultraviolet
2OH	Diol

1 INTRODUCTION

The successful determination of steroids in dosage forms and biological samples presents particular problems to the analyst in view of the great number of members of this class and their varied properties. The addition of any of a number of various functional groups to the generally non-polar cyclopentanophenanthrene nucleus yields compounds of widely different polarities, making extraction from the various matrices a uniquely difficult task. Steroids exhibit uncertain stability, especially to heat, as experienced in gas chromatography (GC), thereby frequently making derivatization necessary. The generally nonconjugated nature of the final structures has few chromophores, making detection and quantitation by ultraviolet (UV) analysis problematic. The extremely low levels found in biological samples make necessary extensive extraction and concentration before analysis. This article discusses, according to their medicinal categories, the various classes of steroids and steroid-like compounds which can be encountered by the pharmaceutical analyst, the general methods used in their determination, and the application of these methods to nine classes of steroidal substances.

2 DISCOVERY AND HISTORY

Steroids possess the skeleton of cyclopentanophenanthrene or a similar skeleton derived by one or more bond scissions, or ring expansions or contractions. An alkyl side chain may be present at C-17, and methyl groups are often present at C-10 and C-13. The ring lettering and the numbering systems for steroids are illustrated in Figure 1,

Figure 1 The ring lettering and the numbering system for steroids, using 5α-cholestane.

using 5α-cholestane. Steroid nomenclature derives from this compound for sterols and from three other simple steroids. These are 5α-androstane, the precursor of the androgens, which has no side chain at C-17, 5α-pregnane, the typical compound for the progestins and corticoids, which has a $-C_2H_5$ at C-17, and 5α-estrane, which has no C-17 side chain and no C-19 methyl group.

Because of the important biological activities and wide medicinal use of steroids, the analysis of these compounds is important in both clinical biochemistry practice and industrial applications. The great diversity of steroid structures and the wide range of their physical properties present special problems for the analysis of the different classes of steroids.

3 MEDICINAL CATEGORIES

The major therapeutic classes of steroids, defined by their physiological function, are the sterols, the androgens, the estrogens, the progesterones, the corticoids (which include the glucocorticoids and the mineralocorticoids), and vitamin D. Other therapeutically important substances with steroid-like structures include bile acids, and the cardiac glycosides.

Sterols are steroids carrying a hydroxyl group at C-3 and most of the skeleton of cholestane. Additional carbon atoms may also be present in the side chain. Among the sterols, cholesterol is unique because it is the biochemical precursor of virtually all other steroid hormones. The determination of free cholesterol in human serum is of great clinical importance in the diagnosis of hepatic disease and other studies of clinical pathologies.

Androgens and anabolic agents include natural hormones and semi-synthetic analogs. Naturally occurring androgenic hormones include testosterone and its potent metabolite dihydrotestosterone. Testosterone has two important functions: androgenic and anabolic. The primary use of androgens and anabolic agents is as androgen replacement therapy in men.

The estrogenic steroids exhibit similar chemical characteristics, which include an aromatic A ring and a hydroxyl group at the C-3 position. Conjugation appears very important in estrogen transport and metabolism and primarily involves the combination of estrogen with glucuronic acid and, to a lesser degree, with sulfate. The conjugated estrogens also have physiological activity.

Estrogens are of clinical and analytical interest for many reasons. They have been widely used in birth control, the prevention and treatment of osteoporosis, the treatment of estrogen deficiency, and the treatment of advanced breast and prostate cancer.

Equine estrogens (conjugated estrogens, esterified estrogens) are largely mixtures of estrone (E1) sodium

sulfate and equilin sodium sulfate with traces of other estrogenic substances. Originally they were obtained from horses, in particular pregnant mares, but now they also are produced semisynthetically from diosgenin and other natural precursors.

The progesterones are involved in the preparation for and maintenance of pregnancy. Progestins are compounds that have biological activities similar to progesterone. This group consists of progesterone (4-pregnene-3,20-dione) and its derivatives, and 19-nortestosterones. The most common use of the progestins, as for the estrogens, is for inhibition of ovulation.

Corticoids are steroid hormones produced by the adrenal cortex. The adrenal cortex hormones are classified by their biological activities into three major groups: mineralocorticoid, glucocorticoids with moderate to low salt retention, and the glucocorticoids with high salt retention. The most important steroids produced by the adrenal cortex are aldosterone which is the primary mineralocorticoid in humans, and hydrocortisone, the primary glucocorticoid in humans which has become very useful for its anti-inflammatory effects. The glucocorticoids have a profound effect on carbohydrate metabolism. Mineralocorticoids affect ions involved in the regulation of calcium transport. Apart from mammalian hormones, the steroid structure is found in many naturally occurring compounds of biological interest such as cardiac glycosides, bile acids, sterols, ecdysterols, and steroid sapogenins and certain antibiotics.

Cardiac steroids are a group of compounds that increase the contractility of the heart and can be very useful in the treatment of congestive heart failure. The most familiar of these is digoxin. Since its therapeutic index is relatively narrow and toxicity is a serious problem in therapeutic use, accurate analytical methods are essential. The cardiac steroids are found in a variety of plant species. *Digitalis purpurea* and *D. lanata* have been the most important overall sources of cardiac steroids.

The bile acids are anionic detergents biosynthesized from cholesterol and found in the intestinal tract and in bile. Their action is to emulsify fats, fat-soluble vitamins, and other lipids so that they may be absorbed. Almost all of the cholesterol not used for the formation of steroid hormones is converted to bile acids, which then react with glycine or taurine to form conjugates, which are secreted in the bile. In the intestine, the conjugates are converted to cholic acid, deoxycholic acid, and several other bile acids, many of which are then reabsorbed. Human bile contains five major bile acids, viz., cholic, chenodeoxycholic, deoxycholic, ursodeoxycholic, and lithocholic acid.

The vitamins D are fat-soluble seco-steroids, so called because they have undergone a fission of the B ring between carbons 9 and 10. Ergocalciferol (vit D_2) is formed in plants and cholecalciferol (D_3) in animals and both have identical but low activity in humans until metabolized to active forms.

4 METHODS USED IN STEROID ANALYSIS

4.1 Ultraviolet/Visible Spectroscopy

Ultraviolet/visible (UV/VIS) spectroscopy, which became available as a routine tool in the 1940s, has an important role in both quantitative and qualitative steroid analysis because of its good sensitivity and selectivity, low cost, and ease of automation. Using a scanning diode-array UV spectrophotometer as a detector following high-performance liquid chromatography (HPLC) separation broadens the applicability of both techniques.

UV/VIS spectrophotometry permits the easy characterization and quantification of those steroids containing conjugated unsaturated systems, such as '4-en-3-one' type, estrogens, and trienes of the vitamin D series. Unconjugated steroids with isolated double bonds can also be analyzed using lower wavelengths. A variety of chemical derivatizations have been employed to enhance the UV method in the analysis of UV non-absorptive steroids or to increase the sensitivity and selectivity. UV analysis of steroids depends usually on the identification of the following chromophoric groups.

A set of simple rules, developed through examination of UV spectroscopic data for a wide variety of compounds, including steroids, allows the prediction of λ_{max}, (often within 2–3 nm of the observed value) for conjugated dienes and polyenes.[1] The parent diene is assigned a base absorption at 214 nm and increments are added for substituents. For example, each additional double bond results in a shift of +30 nm and a heteroatom substituent adds 5 nm. For α,β-unsaturated ketones, the UV absorption associated with the $\pi \rightarrow \pi^*$ transition is the most important. The rules for calculating λ_{max} for such systems are similar with those rules for conjugated dienes and polyenes.[1]

The phenolic hydroxyl group at C-3 in the estrogens is a substituent of common interest in steroid UV analysis, owing to its effect on band maxima. For example, the UV absorption spectrum of estradiol (E2) shows a maximum at 280 nm, with strong absorption below 200 nm, which represents the main maximum of benzene. For steroids that are aromatic in both the A ring and the B ring, such as certain estrogens, the spectra are more complicated, with characteristic absorption at 280 and 342 nm, and also strong end absorption below 200 nm.

4.2 Infrared Spectroscopy

In the 1950s, infrared spectroscopy (IRS) was the only effective method for the identification and structure

elucidation of steroids. Although its importance decreased after the developments of nuclear magnetic resonance (NMR) and mass spectrometry (MS), it is still an essential tool for the rapid identification of steroids. It has rarely been used for quantitative analysis because of the low sensitivity and difficulty of sample preparation. The potassium bromide pellet method is mainly used and is generally specified in the United States Pharmacopeia (USP) 23 for the identification procedure.

Infrared (IR) spectra can provide evidence of functional groups in the sample, but can only give very limited information about the skeleton structure. In the analysis of steroids by IRS, most of the useful bands are above $1500\,cm^{-1}$. The pattern of peaks below $1500\,cm^{-1}$ cannot be assigned to specific vibrations, but occasionally it is characteristic of the steroid and might be useful for identification by comparing the spectrum with that of an authentic sample.

4.3 Nuclear Magnetic Resonance Spectroscopy

The major utility of NMR is to provide information about steroid structure, since it yields information about the molecular framework and functional groups, whereas IR only provides information on functional groups and UV only on conjugated systems. Another significant advantage of NMR is that it is non-destructive and samples can be recovered for further testing. More detailed information about applications of NMR in steroid analysis are available from various sources.[2,3,4,5]

4.4 Chromatographic Methods

Although steroids can be determined by using many methods, the identification and determination of the individual steroids require an efficient separation that can be performed only by extraction and chromatography. Chromatographic methods are important tools for the separation and the determination of steroids because of their high sensitivity, selectivity, efficiency, and separation power.

4.4.1 Thin-layer Chromatography

Thin-layer chromatography (TLC) is still one of the most important tools for the rapid separation and identification of steroids because of its ease of operation, its low cost of operation, and its ability to analyze many samples. The data obtained from TLC are used for the estimation of parameters in other analysis, such as capacity factor in HPLC.

Silica gel, a polar acidic material, is the adsorptive material most usually used and it can be modified for special purposes with other substances, such as bases, buffers, and salts. Aluminum oxide, a basic material, has been used for the separation of C-19 androgens. High-performance thin-layer chromatography (HPTLC) uses microparticulate silica and can achieve increased resolution owing to the higher surface area. Reversed-phase thin-layer chromatography (RPTLC), in which the surface is made non-polar by bonding C_{18}, C_8, or C_1 groups to the silica surface, is also available.

Aside from its relatively low resolution power compared to other chromatographic methods, one of the disadvantages of TLC is difficulty in visualization on the plate of the steroids of interest. For adsorptive steroids, UV spectroscopy can be employed. For nonadsorptive steroids, a wide variety of methods, which usually involve spraying and/or heating with some reagents, is available for visualizing the steroids of interest. Two other optical methods have been used, namely direct fluorescence detection following UV excitation, and fluorescence quenching. The latter technique involves incorporation of a fluorescent compound into the silica gel; the fluorescence of this compound is quenched in the presence of a UV absorber, and renders the compound visible. All of these visualization techniques can be divided into non-destructive and destructive methods. Since inspection of a TLC plate by eye has only a sensitivity of 1 to 10 μg and a reproducibility of about 20%, instrumental detection is considered important and sometimes essential for TLC.

4.4.2 Gas Chromatography

Since its introduction, GC has rapidly become a standard method in the biological and clinical analysis of steroids owing to its high sensitivity, selectivity, and separation power. In modern practice, capillary columns, usually wall-coated open tubular (WCOT) columns in which the stationary phase is coated on the inside of a column with an inside diameter of about 0.2 mm, have replaced the once widely used packed column. These capillary columns may have lengths up to 30 m, and now they provide one of the most powerful means for the separation of steroids. Megabore columns with internal diameters of 0.5–0.75 mm and greater capacity but decreased resolution are also available.

In GC, more than in HPLC and TLC, efficient separation depends mainly on the selection of an appropriate stationary phase since there is a limited choice of mobile phases. The stationary phase is a thermostable compound, which is coated on an inert support, usually diatomaceous earth, or directly on the walls of the column. Chemical bonding of the stationary phase to the support or the column wall reduces ''bleed'' or the slow elution of the stationary phase from the column. Chemical modification can be used to produce a variety of stationary phases with different selectivities.

In the GC of steroids, silicone oils are the most generally employed mobile phases, since they are suitable for the

separation of steroids based on their molecular weight or shapes. The carrier gas is usually nitrogen because it is cheaper, although helium is less dense than nitrogen and gives better resolution. Capillary GC separation of steroids and derivatives are best achieved by using non-polar stationary phases. Only estrogens, sterols, and bile acids require slightly more polar phases.

In order to improve the separation and/or to increase the sensitivity of detection in some cases, chemical derivatizations are frequently necessary for the GC analysis of steroids. The choice of derivatives depends on both the detection method and the chromatographic requirements. Post- and precolumn reactions may be employed. For hydroxyl groups, ethers are usually formed, most commonly trimethylsilyl (TMS) ether derivatives. Other ethers also have been used, such as dimethylethylsilyl ethers for the separation of bile acids and halogenated ethers for use with electron capture detection (ECD). The use of tertiary butyldiethylsilyl ethers is very common for quantitative gas chromatography/mass spectrometry (GC/MS), because these derivatives give mass spectra without extensive fragmentation. Other derivatives such as formates and acetates have also been used. Oxo groups can be derivatized as oximes or enol-TMS ethers. For the carboxyl group, methyl esters are usually formed. The carboxyl group is frequently derivatized precolumn, usually by forming methyl ester derivatives with diazomethane.

Three kinds of detector have been used in steroid analysis. The flame ionization detector is the most commonly used, since it can give out a signal that varies linearly in response factor to most of the steroids and has a large linear dynamic range. Nitrogen–phosphorus detection (NPD), also known as thermionic ionization detection (TID), can detect nitrogen- and/or phosphorus-containing steroids or derivatives selectively. ECD is extremely useful for halogen containing compounds. However, since steroids do not usually contain nitrogen or halogen, derivatization is necessary before the use of gas chromatography/nitrogen–phosphorus detection (GC/NPD) and gas chromatography/electron capture detection (GC/ECD).

GC/ECD has been replaced by GC/MS because of the difficulty in quantification by using ECD, since it has a narrow range of linearity. When operated properly, GC/MS can be as sensitive and more selective then GC/ECD. A major advantage of GC/MS is that some of the steroids can be detected without derivatization, but its high cost limits its use in routine determinations.

4.4.3 High-performance Liquid Chromatography

HPLC has become an important tool for the separation and the determination of steroids because of its high sensitivity, selectivity, efficiency, and better chromatographic properties compared to the other methods.

One of the main advantages of HPLC over other chromatographic methods is that no decomposition or rearrangement occurs during the chromatography as in GC and TLC. In addition, HPLC is a powerful tool for the separation of conjugated compounds and isomers, which are relatively difficult to separate by GC. Although derivatization procedures have been described for almost all of the steroids in HPLC, almost all of them are used for increasing detectability and have no important effect on the separation.

Usually, HPLC columns used in steroid analysis are 10–50 cm in length, 4–5 mm in internal diameter, and with 60 000–80 000 theoretical plates per meter. Microbore HPLC using columns 20–50 cm long and with internal diameters of 0.5–2 mm can provide higher sensitivity and efficiency, although it requires specialized pumping equipment and sample injectors as well as microvolume detector cells.

Both normal and reversed-phase high-performance liquid chromatography (RPHPLC) can be used for steroid separation. In normal HPLC, high-performance silica and alumina stationary phases have been successfully used. In RPHPLC, silica packing bonded on the surface with octadecyl or diol groups are most used. The separation depends largely on partition so that the selectivity varies with the length of the carbon chain on the column, the form of the support material, and the properties of the mobile phase.

Mobile phases consisting of only one or two solvents are those mainly used in steroid separations; however, multisolvent mobile phases may be especially useful for particular separations. A preliminary analysis by TLC can be used to test the suitability of the mobile phase chosen. Although most steroids are well separated by HPLC, the best separation of a variety of steroids has been achieved by gradient elution, which includes linear, non-linear, and stepped modes. Beside solvent constitution, the pH, as well as added ion-pair reagents and modifiers are also influential factors on the selectivity of the mobile phase. Ion-pair chromatography is preferred for the separation of steroid conjugates and bile acids. Micellar chromatography, in which some compounds, such as sodium dodecyl sulfate (SDS) are added, has been claimed to improve the separation of HPLC, especially the separation of optical, geometrical, and structural isomers. Nishi has reviewed pharmaceutical applications of micellar liquid chromatography (MLC).[6]

UV absorptive steroids or derivatives can be detected directly by UV detection, which is the most widely used detection technique in the conventional HPLC analysis of steroids. Post- and precolumn derivatization have been used to form UV-absorbing derivatives, which may also increase the sensitivity. Since the sensitivity of HPLC with UV detection is around 1 ng per injection, UV

detectors cannot provide enough sensitivity and selectivity for many steroids, in particular the polar steroids, such as bile acids. As a consequence, laser-induced fluorescence (LIF) detection may be used[7] to increase the limits of detection and quantitation. Fluorescence and electrochemical detectors have achieved determination of steroids at the picogram level. The sensitivity of detection has been extended by developments in biospecific detection principles, e.g. radioimmunoassay (RIA) coupled to HPLC.[8–12] This area has been reviewed.[13,14]

4.5 Mass Spectrometry

Modern MS methods can analyze almost all steroids and steroid conjugates. MS has been used as a qualitative analysis method by comparing the observed spectrum with the spectra of known compounds, and/or by deducing the structure from the presence of characteristic fragments. MS also has been used in steroid quantification since the intensity of signals is proportional to the quantity of the compound present.

The main two roles of MS in steroid analysis are structure elucidation and quantitative analysis. The MS measurements for structure elucidation include the determination of molecular weights, the determination of elemental and isotopic compositions, and the evaluation of the fragmentation characteristics of the analytes. For molecular weight determination, it is often desirable to suppress fragmentation through the use of soft ionization, but for other structural studies the fragmentation products of the analytes provide most information. Modern MS can offer high sensitivity for the qualitative and quantitative analysis of both isolated analytes and of specific analytes in a mixture.

MS analysis involves three essential steps: ionization of the sample, resolution of the resulting ions, and detection of the ions. Sample introduction and data processing are also integral and important parts of MS. The principal techniques of ionization and sample introduction employed in MS analysis of steroids are summarized in Table 1.

Steroids can be analyzed directly by MS using a heated sample probe, which allows the insertion of the analyte directly into the vacuum and in the vicinity of the ionization chambers. However, because of the nature of most samples presented for analysis, it is usually more effective to integrate MS on-line with other techniques, which include GC, HPLC, supercritical fluid chromatography (SFC), and capillary electrophoresis (CE). In these cases, sample introduction can be performed through these instruments but usually a special interface is necessary to separate the analyte from the sample matrix.

MS methods are categorized mainly by the ionization techniques used, because the ionization step has the most important impact on the appearance of the mass spectrum and the application of MS. The methods using low internal energy, such as CI and field ionization are called 'soft' ionizations and give a high yield of protonated and cation-coupled molecular ions with little or no fragmentation. Other methods, in which high internal energy is transferred, such as electron impact (EI) ionization, usually cause extensive fragmentation of the sample.

Depending on the type of instrument used, the ions have kinetic energy from a few eV to as high as 10 KeV. Resolution of the ions expelled from the ion source according to their m/z ratios is accomplished by studying their flight through one or more analyzers, including momentum (magnetic sector), resonance frequency (quadrupole, ion cyclotron resonance and ion trap), kinetic energy (electric sector) and velocity (time-of-flight). The most commonly used MS ion-resolution methods for steroid analysis are the magnetic sector and quadrupole instruments. They are compatible with almost all of the ionization methods except plasma desorption ionization.

Data processing systems assure the efficient use of the enormous amount of data generated by MS and the precise control of complex instrumental parameters for various applications. The main functions of the data systems include the digitization and rapid storage of the data, mass and intensity assignments for every ion, and representation of the data in an easily comprehensible graphic or tabulated form.

Determination of the isotope composition of steroids is another important application of MS in steroid analysis,

Table 1 Principal techniques of ionization and sample introduction employed in steroid analysis by MS. (From Makin and Gower[1])

Ionization techniques	Sample introduction	Analyte type
Electron ionization	Direct insertion probe, GC	Unconjugated steroids (after derivatizations)
CI	Direct insertion probe, GC	Unconjugated steroids (after derivatizations)
Electron capture	GC	Unconjugated steroids (after derivatizations)
Thermospray	Flow injection analysis, LC	Unconjugated steroid glucuronides
FAB/SIMS	Direct insertion probe, GC Flow injection analysis, LC	Conjugated
Electrospray	Flow injection analysis, LC	Conjugated

CI, chemical ionization; FAB/SIMS, fast atom bombardment/secondary ion mass spectrometry; LC, liquid chromatography.

and can be easily accomplished with the use of low-resolution measurements. The ion clusters observed in every steroid spectrum are due to the naturally occurring minor isotopes such as ^{2}H, ^{13}C, and ^{18}O, etc. in which especially informative are the isotope pairs of ^{35}Cl and ^{37}Cl, and ^{79}Br and ^{81}Br, and the complex isotope pattern of certain metals. Because an isotope can be relatively easily measured by MS, stable-isotope labeled substances offer a convenient way to study the metabolism of steroids in humans. The ^{14}C radioisotope is also commonly used in drug metabolism studies at enrichment levels. For the same reason, ^{2}H, ^{13}C, and ^{18}O labeled steroids are extensively used in reaction and fragmentation mechanism studies and as internal standards in quantitative measurement.

4.5.1 Quantitative Determinations

Since its introduction, MS, especially when combined with GC or LC, has been one of the most useful forms of quantification available since it excels in sensitivity, accuracy, dynamic range, and specificity at trace level. As a result, MS has become the method of choice for the quantitative determination of many biologically important steroids. The various concepts of quantitative MS have been reviewed by Millard.[15]

4.5.2 Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) provides a method for determining the precursor ions of the fragmentation ions. MS/MS can be performed by using a triple quadrupole combination or a double-focusing sector instrument. Hybrid instruments, which couple a double focusing instrument with a quadrupole collision cell and quadrupole mass analyzer, have also been used. Since MS/MS is so highly specific, low-level constituents in biological samples or chemical mixtures can frequently be determined with little or no sample purification.

Derivatizations are occasionally employed in MS for one or more of the following purposes: to meet the requirement of sample volatility, to improve sample stability, to improve chromatographic properties, to enable functional group analysis, and to modify the fragmentation pattern.

4.5.3 Gas Chromatography/Mass Spectrometry and High-performance Liquid Chromatography/Mass Spectrometry

GC/MS is one of the most important techniques in pharmaceutical studies and in steroid analysis because the resolving power of capillary GC is combined with the high-specificity and sensitivity of MS. For instance, since isomeric steroids may be difficult to distinguish by MS but can be easily separated by GC, they can be identified by GC/MS. Similarly, the combination of HPLC with MS/MS offers special importance in the analysis of large numbers of samples in complex matrices. When coupled with GC or HPLC, the MS can be used in a selected/multiple ion monitoring mode and/or total monitoring mode. The most common and informative mode of operation is scanning the mass spectrum at frequent intervals across the full mass range. The individual spectra from each peak can be subsequently examined and used for identifying the analytes.

4.6 Immunoassay Methods

Competitive binding assays, in which the binding proteins included antibodies and specific receptors, were introduced by the early 1970s. Immunoassays have been proven to be more appropriate analytical tools for steroids in biological materials, such as serum or plasma, and alternatively urine and saliva. The current immunoassays for steroids have much improved sensitivity and precision as well as reduced cost and simplified procedures.

Although immunoassays can be highly specific and sensitive, errors may occur because both the characteristics of the antibody employed and the sample matrix can affect the assay. Cross-reactivity is always a major concern in immunoassays. For steroid analysis, cross-reactivity may come from structurally related steroids, derivatives of the analyte, or metabolites of the analyte.

Both monoclonal and polyclonal antibodies have been used in immunoassays of steroids The main problem in the antibody production is that steroids and relative compounds are too small to be immunogenic. They have to be coupled to large carrier compounds, proteins such as bovine serum albumin (BSA), to elicit the production of antibodies. Many factors of the steroid–protein conjugates may affect the antibodies produced, including the method used, the position and number of the linkage, and the steric structure of the conjugate.

Several kinds of label have been used for detection, including radioactive, enzymatic, fluorescent and chemiluminescent compounds. Radioactive labels are most commonly used, but there is an increase in the use of non-radioactive labels, mainly because these procedures are safer, cheaper, simpler, and sometimes more precise and sensitive.

Tritium has been the most widely used radiolabel in the immunoassays of steroids, although iodinated labels are also frequently used. Multiple labeling of the steroid is usually necessary in order to produce high specificity. The main advantages of iodine labels over tritium labels include higher specificity, lower cost and lower quenching.

Enzymes have been proven to be sensitive and versatile labels in the immunoassays of steroids because the end-point signal is amplified by the enzymatic reaction.

Versatility results from the variety of enzymes and end-point reactions that can be used. The most widely used enzymes in steroid analysis are horseradish peroxidase (HRP) and alkaline phosphatase.

Fluorescence detection is generally a very sensitive method, but practically its sensitivity is restricted to a concentration range of 10^{-9}–10^{-12} mol L^{-1} owing to the background signal produced by other fluorescent materials, particularly in biological samples. The fluorescent molecules that have been most commonly used in steroid analysis including fluorescein, rhodamine, umbelliferone, and rare earth chelates. The latter are especially useful because of the long half-life time and the differing fluorescent spectra of various rare earth chelates, which makes possible the simultaneous measurement of several analytes by using different chelates, such as those of europium, samarium, and terbium.

Chemiluminescence is effected by a chemical reaction, usually an irreversible oxidation reaction. This reaction may be mediated by enzymes, temperature, or electric charge applied, and they are termed, respectively, bioluminescence, thermochemiluminesence and electrochemiluminescence. Many organic compounds are luminescent upon oxidation and have been used in immunoassays as labels, including the cyclic hydrazides such as isoluminol (6-amino-2,3-dihydrophthalazine-1,4-dione) and its derivatives, aminonaphthyl hydrazides, and acridinium esters and their derivatives. Chemiluminescence has also been used in enzyme immunoassays (EIAs) as an end-point.

5 STEROLS

Because of the implications of free cholesterol in atherosclerosis, heart disease, and hepatic diseases, accurate methods for its analysis in human serum are necessary for precise clinical diagnosis. Accurate determination of cholesterol is also important in the food industry. Historically, the methods used for such analyses have been relatively simple to allow for rapid estimation, and have been based mainly on colorimetric or enzymatic reactions. Because these methods lack sensitivity and suffer from interference, they are not reliable in the analysis for cholesterol in physiological fluids other than plasma. Hence, several chromatographic methods[16] have been developed, including GC[17,18] and HPLC.[19]

5.1 Gas Chromatography

GC has great importance in the analysis of free sterols but, because of their polarity, it is often necessary to analyze them as their derivatized forms. The shape of the sterol molecule is critical in determining the separation for sterols in GC. Planar sterols generally have longer retention times than non-planar ones on a column of given polarity. Long capillary columns have been used for separation of isomeric C_{24} sterols. The great advantage of GC over other chromatographic techniques is that it is ideal for coupling with MS. The major disadvantage of GC is that many sterols are thermally unstable.

Rodriguez-Palmero[20] reported an accurate method for the determination of sterol content by capillary gas chromatography (CGC). The procedure includes: dichloromethane–methanol (2 : 1, v/v) extraction, saponification at 80 °C, derivatization to form TMS ethers and GC. The method shows good accuracy, precision, and sensitivity and is suitable for the determination of sterols in food.

Garcia Regueiro[21] developed a reproducible procedure for the determination of eight cholesterol oxides using on-column injection and solvent venting capillary gas chromatograph. The method consists of the combined use of solid-phase fractionation and TLC. The determination of cholesterol oxide TMS derivatives was performed by using CGC. On-column CGC gave absolute area relative standard deviation (RSD) values of 3% to 6%.

5.2 High-performance Liquid Chromatography

As the technology of HPLC has improved over the last decade, it has been more widely applied to the analysis of sterols, with both reversed-phase and normal-phase HPLC having been utilized. Specially synthesized stationary phases with chemically bonded β-cyclodextrin and tomatine have been used in order to attain better separation. The HPLC method has also been applied to the determination of cholesterol in liposome drug products and raw materials.

Since most sterols lack a strong chromophore, UV detection is generally unsatisfactory unless the detector is operated below 250 nm and even as low as 220 nm. Special purpose detectors, such as flame ionization, differential refractometric, and radiochemical have also been employed in order to improve detection.

Okazaki[22] compared the precipitation and direct methods for high-density lipoprotein cholestrol (HDLC) assay with HPLC. The HPLC method, which provided quantitative and qualitative information with high precision, was regarded as being a reliable approach for HDLC assay. The HPLC procedure can be also used to evaluate alternative methods for cholesterol assay.

Rezanka[23] reported the analysis of sterol esters using tandem high-performance liquid chromatography (HPLC/HPLC) and capillary gas chromatography/mass spectrometry (CGC/MS) with CI. Non-polar lipids were

separated by normal-phase HPLC into individual classes and the sterol esters were subsequently separated by RPHPLC. Further separation and identification of the fractions after HPLC were effected by CGC/MS with positive and/or negative CI.

6 ESTROGENS

6.1 Identification Tests for Estrogens

As specified by the USP 23, IR and UV at 200–400 nm are the identification tests prescribed for pharmaceutically important estrogens. The TLC method is used as the identification test for sterile E1 suspension and E2 tablets. For sterile E1 suspension, a 0.25-mm layer of chromatographic silica gel is used and the solvent system consists of a mixture of benzene and acetone (4 : 1). After developing, the plate is sprayed with dehydrated alcohol and sulfuric acid (3 : 1), and is then heated at 105 °C for ten minutes.

Their aromatic ring A and the phenolic group at position 3 can characterize estrogens. They show characteristically complicated absorption, with principal maxima at 280 and 342 nm, as well as very strong end absorption down to 200 nm. The pH of the solution is important in determining these phenolic substances. The spectrum of an estrogen with a free phenolic hydroxyl group has an absorption band of medium intensity at around 278 nm. However, at a pH above 9–10, the band shifts about 20 nm higher and the intensity increases owing to the ionization of the phenolic group.

In the IR technique, the potassium bromide pellet method is used. The characteristic group wavenumbers of estrogens are 1613–1610, 1590–1589, and 1503–1490 cm^{-1} which are due to the C=C or C≡C stretching. The diagnostic value of the absorptions due to the phenolic ring is not comparable with that of the data obtained by UV spectra.

6.2 Assays of Raw Materials and Medicinal Products

Because of their broad therapeutic spectrum, there are numerous pharmaceutical products containing estrogens. As shown in Table 2, HPLC is the most common method used in the analysis of raw materials and medicinal products of estrogens in the USP 23.

6.3 Analysis of Estrogens in Biological Media

Generally, analysis of estrogens in biological material requires extraction of the analyte from the sample, separation into individual components, and their determination. Sometimes it is possible to extract the estrogens from the sample directly by simple solvent extraction but, more often, it is necessary to hydrolyze conjugates

Table 2 Methods used in the assay of estrogens in USP 23

Compound	Method	Detector	Packing	Mobile phase or solvent
E1	HPLC	280 nm	ODS	ACN–0.05 M KH_2PO_4, 1 : 1
Injection and sterile suspension	Gravimetric			
E2 and tablets	HPLC	205 nm	ODS	ACN–H_2O, 55 : 45
Vaginal cream	HPLC	280 nm	ODS	ACN–H_2O, 1 : 1
Pellets and sterile suspension	Visible	520 nm		Iron-phenol reagent
Valerate and valerate injection and cypionate and cypionate injection	HPLC	280 nm	ODS	ACN–NH_4NO_3 0.033 M, 7 : 3
Estriol	UV 281 nm	–	–	EtOH
Ethinyl E2	HPLC	280 nm	ODS	ACN–H_2O, 1 : 1
Tablets	Visible	538 nm	–	MeOH–H_2SO_4, 3 : 7
Equilin	HPLC	280 nm	ODS	ACN–H_2O, 35 : 65
Conjugated estrogens and tablets and esterified estrogens and tablets	GC	FID	Phenylcyano-propyl methyl silicone	He
Estropipate and tablets	HPLC	213 nm	ODS	ACN–0.025 M KH_2PO_4, 65 : 35
Vaginal cream	HPLC	280 nm	ODS	ACN–MeOH–0.05 M KH_2PO_4, 18 : 18 : 64
Mestranol	Visible	545 nm	–	MeOH–H_2SO_4, 3 : 7
Dienestrol and cream	HPLC	254 nm	ODS	Degassed methanol

ODS, octadecyl silane; ACN, acetonitrile.

before the extraction. Several methods are available, including acid hydrolysis and enzymatic hydrolysis using β-glucuronidase and/or sulfatases.

There are a number of reports of the use of gel filtration for extracting conjugates. A review of isolation techniques using gel filtration has been published.[24] Separation of individual estrogen glucuronides and sulfates was achieved by using diethylaminoethyl Sephadex.[25] Simple extraction of estrogens from plasma or hydrolyzed urine has been achieved by using G-15 and G-25 Sephadex.[26,27]

A number of methods for the extraction of estrogens are summarized in Table 3. Martinetti[42] described a novel extraction method for the evaluation of plasma levels of E2, E1, and E1-S. The method consisted of solid-phase extraction (SPE) followed by a highly specific RIA. The sensitivity of the assay was 0.6 pg mL^{-1}, 2.0 pg mL^{-1} and 7.0 pg mL^{-1} for E2, E1, and E1-S respectively.

Hirako[41] reported the establishment of a reliable extraction method of bovine plasma E1-S followed by RIA. E1-S in bovine plasma was extracted with a small reversed-phase cartridge. The steroid conjugate retained in the cartridge was eluted with 40% (v/v) methanol. E1-S was separately recovered from other steroids by the stepwise increase in methanol concentration in the elution solvent. The recoveries of E1-S eluted with 40% methanol were more than 90%. The concentration measured by RIA with the eluent of 40% methanol was consistent for plasma extraction volumes of 0.5–2.0 mL.

Immunoaffinity extraction has been used for liquid chromatographic determination of estrogens. Ikegawa[43] reported an immunoaffinity extraction for the HPLC determination of equilin and its metabolites in plasma. The antibody raised against an equilin 3-*O*-carboxymethyl-ether-BSA conjugate was characterized as having a high affinity for equilin and equilenin. The adsorbates were recovered by elution with 90% aqueous (v/v) methanol without any interfering peaks on the chromatogram.

Quantification of the estrogen analytes has been accomplished by a variety of methods including colorimetry, fluorimetry, double-isotope derivatization, immunoassay, GC, GC/MS, and HPLC. The early methods may be outdated, but those with low specificity may be combined with modern separation methods like HPLC to offer useful assays. As an example, the quantitative structure–chromatographic retention relationship of six underivatized equine estrogens has been reported.[44]

The immunoassays in use are of the competitive type. Some efforts have been made towards non-competitive immunoassay of estrogens.[45] A wide variety of labels are used, including ^{125}I, ^{3}H, enzymes, or fluorescent compounds. Separation of the free and bound analyte can be done using dextran-coated charcoal (DCC), second antibody precipitation, or solid-phase assay. Some form of manipulation can avoid the separation step, e.g. delayed fluorescence. Alternative end-points have enabled some estrogen assays to be simplified and made more sensitive, such as EIA and fluorescence immunoassay (FIA) methods. The detection limits (DLs) achieved are nanograms per litre by RIA and EIA, and micrograms per litre by FIA.

A novel noncompetitive assay for the measurement of estrone-3-glucuronide (EG) in diluted urine was reported by Barnard.[45] The method is based on the use of two

Table 3 Extraction of estrogens (partly adapted from Makin and Gower[1])

Estrogen	Solvent (or method)	Sample dilution	Refs.
E1 and E2	Diethyl ether	1 : 1, Plasma at pH 9.0	28
Estriol	Diethyl ether	1 : 3, Plasma–water	29
Estriol	Ethyl acetate–hexane, 1 : 8	Plasma–buffer, 1 : 1	30
2-Hydroxyestrone	Dichloromethane	Plasma	31
6-Oxo-E2-17β	Diethyl ether	Plasma	32
E1 and E2	Diethyl ether	Diluted urine	33
E1 glucuronide and sulfate	Ethanol	Amniotic fluid	34
Estriol 16α-glucuronide	Precipitated with $(NH_4)_2SO_4$, redissolved in methanol–acetone	Urine	35
E1-S	THF–ethyl acetate	Plasma	36
Estrogen glucuronide and sulfates	Methylene blue	Plasma	37
Estrogen glucuronide and sulfates	Chloroform-*n*-butanol	Urine	38
E1 and E1 conjugates	Columns or cartridges of octadecylsilane-coated silica	Urine, serum, amniotic fluid	39, 40
E1-S	Reverse phase cartridge	Bovine plasma	41
E2, E1 and E1-S	Selective solid phase extraction	Plasma	42
Equilin, equilenin, their metabolites and glucuronic acid conjugates	Immunoaffinity extraction	–	43

THF, tetrahydrofuran; E1-S, estrone sulfate.

types of antibodies, the β-type and α-type that recognize different epitopes within the variable region of the primary anti-EG antibody (Ab1). The β-type antibody (Ab1) is analyte sensitive and competes with the analyte for an epitope of the primary antibody. On the other hand, the α-type is analyte insensitive, but does not bind the Ab1 in the presence of the β-type due to epitope proximity.

RIA still is the most widely used competitive immunoassay. Combined with chromatographic methods, especially HPLC, RIA is becoming a very powerful tool in the analysis of estrogens. Meanwhile, EIA and FIA have enabled some estrogen assays to be simplified and made more sensitive and have been used as bases for automated immuno-analyzer systems.

An EIA was used by De Lauzon[46] to predict ovulation in women. Henderson[47] reported that EG concentrations in urine were measured by an EIA. In this work, a monoclonal antibody of EG was generated and incorporated into competitive EIAs, with HRP as the enzyme label. The sensitivity achieved was 1.1 ± 0.1 pg per well.

Time-resolved fluorescence with rare earth chelate labels has been used[48] to facilitate the simultaneous measurement of more than one ligand. Barnard[49] reported the development of a time-resolved FIA for the simultaneous measurement of EG and pregnanediol-3-α-glucuronide (PG) in samples of early morning urine using appropriate rare earth chelates with differing emission spectra. The procedure used different lanthanide chelates as labels and measured europium and samarium fluorescence. The method demonstrated sensitivity and precision (all coefficients of variation, 5–8%) across the relevant working ranges for each analyte.

Martinetti[42] reported the development of a rapid and ultrasensitive RIA method for E2, E1, and E1-S determination with selective SPE followed by a highly specific RIA. The sensitivity of the assay was 0.6 pg mL^{-1}, 2.0 pg mL^{-1}, and 7.0 pg mL^{-1} for E2, E1, and E1-S, respectively.

Ranadive[50] described a rapid, convenient RIA of E1-S. The assay had a dynamic range of 0.05–90 μg L^{-1} with a DL of 0.009 μg L^{-1}. Cross-reactivities with structurally related estrogens were <5%.

Lonning[51] described a sensitive assay for measurement of plasma E1-S in patients on treatment with aromatase inhibitors. E1-S was separated, hydrolyzed, and purified as unconjugated E1. E1 was subsequently reduced to E2, purified, and measured by a highly sensitive RIA using E2-6-(*O*-carboxymethyl) oximino-(2(-)[^{125}I]) iodohistamine as a ligand. The sensitivity limit of the method was 2.7 pM.

Table 4 lists some typical immunoassay methods for the analysis of estrogenic steroids.

6.4 Estrogen Analysis by Gas Chromatography

GC has proven extremely useful for the measurement of estrogens in biological fluids, such as plasma and urine. Before the development of the immunoassays, GC with flame ionization detection or, after suitable derivatization, ECD provided highly sensitive methods for estrogen analysis. However, extensive purification is needed before GC analysis. Owing to the presence of hydroxyl groups in their structure, most estrogens are highly polar and require derivatization prior to analysis for complete separation. Derivatization reagents used included TMS ethers, methyloxime ethers, and ethyloxime ethers.

CGC, using stationary phases more polar than those used for neutral steroids, provides improved resolution. Among the polar phases used are OV-210 (McReynolds number 1520), OV-225 (McReynolds number 1813),

Table 4 Immunoassays for estrogen estimation

Method	Compounds	Antibody or ligand	Label	Sensitivity	Ref.
FIA	EG	2nd antibody against the anti-EG antibody (Ab1)	Fluorescence of Eu	50 nmol L^{-1}, cross-reaction < 0.1%	45
EIA	EG in urine	Monoclonal antibody of EG	HRP	1.1 ± 0.1 pg per well.	47
	E2-17β in saliva	Monoclonal antibody	HRP	7.3 pM, cross-reaction < 0.2%	52
FIA	EG, PG (simultaneous)	Monoclonal antibody of EG/EG/BSA	Fluorescence of Eu and Sm	40 nmol L^{-1}	48
RIA	E2, E1, and E1-S	–	–	E1 – 0.6 pg mL^{-1}, E2 – 2.0 pg mL^{-1} E1-S – 7.0 pg mL^{-1}	42
	E1-S	E1-6-*O*-carboxy-methyl-oxime : BSA conjugate	^{125}I	DL of 0.009 μg L^{-1}, cross-reaction < 5%	50
	Bovine saliva E1-S	–	–	29.7 pg per tube	53
	Plasma E1-S	E2-6-*O*-carboxy-methyl-oximino-2-[^{125}I] iodohistamine	^{125}I	2.7 pM	51

and Silar 10c (McReynolds number 3682). These have been successful in separating both human and equine estrogens. Estrogens are identified by retention time and preferably, in addition, by on-line MS. GC/MS has the potential to provide higher sensitivity for analysis as well as confirmation of structure although it is technically the most challenging method for analysis and is not the method of choice for routine analysis. The limit of detection is at the $\mu g\,L^{-1}$ level, comparable to FIA.

Bagnati[54] reported the analysis of diethylstilbestrol, dienestrol and hexestrol in biological samples by immunoaffinity extraction and GC-negative-ion CI MS. Novak[55] reported pregnenolone and E2 identification in some biological samples by means of GC/MS analysis.

Casademont[56] described simultaneous determination, in calf urine, of twelve anabolic agents (including diethylstilbestrol, hexestrol, dienestrol, 17β-E2, E1, and 17α-ethinylestradiol) as heptafluorobutyryl derivatives by capillary GC/MS. Urine samples were extracted with octadecylsilica columns and cleanup was performed in two steps with basic alumina and silica SPE cartridges. The extracts obtained were derivatized with heptafluorobutyric anhydride and analyzed by GC/MS. The coefficient of variation obtained was lower than 13%. The limit of detection was $0.5\,ng\,mL^{-1}$ for all the compounds studied.

6.5 Estrogen Analysis by High-performance Liquid Chromatography

HPLC with a suitable choice of column and solvent system can perform estrogen analysis with high specificity. Preparative HPLC has been used to separate steroids prior to analysis by chemical or immunological methods. Reversed-phase LC has been preferred for the separation of the intact conjugated estrogens and is widely used for quality control. The DLs of HPLC using UV detection ranged from 0.5 to $5\,mg\,L^{-1}$ and were at $\mu g\,L^{-1}$ levels when using a fluorescent detector.

Combining the separation power of HPLC and the selectivity and sensitivity of biochemical assays leads to powerful tools for the assays of compounds in complex matrices, e.g. HPLC combined with RIA in the analysis of estrogens. A novel approach is the use of biochemical interactions, such as a receptor affinity detection system (RAD), as an on-line detector linked to a LC separation column.[57]

β-Cyclodextrins have been investigated as a mobile phase additive to improve the separation of 17-α- and 17-β-E2 and E1,[58] and equilin and three E1 derivatives.[59] In these studies, evidence is presented for inclusion complexation between the model estrogens and β-cyclodextrins leading to improved resolution and shorter separation time.

Katayama described a sensitive method for the estimation of seven estrogens in plasma.[60] In that method, estrogens were derivatized to esters and the limit of detection was $1–2\,ng\,L^{-1}$ of plasma. Similar work by Su[61] reported the HPLC analysis of six conjugated and unconjugated estrogens in serum, in which the mobile phase was optimized with ACN and an ion-pairing agent (tetrabutylammonium hydroxide).

An HPLC method for the direct and simultaneous determination of estriol 3- and 16-glucuronides in pregnancy urine was described by Iwata.[62] The method is based on direct derivatization of the glucuronic acid moiety in estriol glucuronides in urine with 6,7-dimethoxy-1-methyl-2 (^{1}H)-quinoxalinone-3-propionylcarboxylic acid hydrazide. The resulting fluorescent derivatives were separated by column-switching chromatography using a first column for cleanup of the derivatives and a second column for the complete separation of the derivatives. The derivatives were detected spectrofluorimetrically at 445 nm with excitation at 367 nm. The DLs (signal-to-noise ratio = 3) for estriol 3- and 16-glucuronides were 150 and 180 fmol in a $5\,\mu L$ sample of urine (14 and $17\,ng\,mL^{-1}$ urine), respectively. The method is highly sensitive and simple without any cleanup such as conventional SPE.

6.6 Bioassays Using High-performance Liquid Chromatography

On-line coupling of a RPHPLC with a RAD system based on the human estrogen receptor is described by Oosterkamp.[57] The RAD is performed using a postcolumn reaction detection system with open-tubular reaction coils. Estrogens are detected by using a recombinant steroid binding domain of the human estrogen receptor as affinity protein, and a fluorescent estrogen, coumestrol, as reporter molecule. A DL of $5\,nmol\,L^{-1}$ was achieved for compounds with high affinity for the estrogen receptor, such as 17-β-E2 and diethylstilbestrol, and $20\,nmol\,L^{-1}$ for compounds with low affinity. The system can also be operated without requiring a separation step.

HPLC coupled with RIA has been used in the assessment of serum E2 and E1 levels during hormone replacement therapy.[63] It was also reported as a sensitive method in the determination of intratumor E1 and E2 in primary breast cancer tissues.[64]

7 ANDROGENS

7.1 Identification Tests for Androgens

As specified by the USP, IR and UV at 200–400 nm are the identification tests available and common for pharmaceutically important androgens. TLC also has been used as an identification test for some androgens.

Table 5 Methods used in the assay of androgen-containing medicinals in USP 23

Compound	Method	Detector	Packing	Mobile phase or solvent
Testosterone and sterile suspension	UV	241 nm	–	MeOH
Cypionate and cypionate injection	GC	FID	1% Trifluoropropyl-methyl polysil-oxane on siliceous earth	He
Enanthate and enanthate injection and propionate and propionate injection	UV	380 nm	–	Isoniazid Reagent
Nandrolone decanoate	UV	239 nm	–	EtOH–$CHCl_3$
injection	UV	380 nm	–	Isoniazid Reagent
Phenpropionate	UV	239 nm	–	EtOH–$CHCl_3$
injection	UV	380 nm	–	Isoniazid Reagent
Oxandrolone	Back titration	–	–	HCl
Tablets	GC	FID	Methylsilicone oil on siliceous earth	He
Oxymetholone and tablets	UV	315 nm	–	MeOH
Stanozolol	Nonaqueous titration	–	–	$HClO_4$
tablets	UV	235 nm	–	EtOH
Methyltestosterone	HPLC	241 nm	ODS	ACN–H_2O, 55 : 45
Capsules and tablets	UV	241 nm	–	EtOH
Fluoxymesterone and tablets	HPLC	254 nm	Porous silica	Special[a]

[a] Butyl chloride–H_2O saturated butyl chloride–THF–MeOH–HOAc, 475 : 475 : 70 : 35 : 30.

7.2 Assays of Raw Materials and Medicinal Products

As shown in Table 5, various methods are used in the analysis of raw materials and medicinal products containing androgens in the USP.

7.3 Analysis of Androgens in Biological Media

Androgens, such as testosterone, occur largely in conjugated form in urine, and require the liberation of the steroids before analysis. The methods used include solvolysis at an acid pH for cleavage of steroid sulfates,[65] as well as enzymatic methods, involving the use of β-glucuronidase and sulfatase for cleavage of glucuronides and sulfates.[66,67]

Solvents that are partially miscible or immiscible with water, such as ethyl acetate, ether, chloroform, and dichloromethane, have been used to extract ''free'' (unconjugated) steroids from biological matrices. In addition, ion-exchange resins, such as Amberlite XAD-2, have been utilized extensively for extraction and subsequent separation of steroid hormones, both ''free'' and conjugated.[68] Gel filtration has also proven to be extremely valuable.[69]

Since 1980, SPE cartridges have been used widely as adsorptive extractants. After application of the urine sample, most of the interfering substances are washed away with water while the analytes remain adsorbed. Elution with a stronger solvent, such as methanol, removes the analytes. As little as 2 mL of methanol is needed to provide some 98% recovery of steroids with SPE cartridges. However, some workers have reported that the eluates from these contain impurities that interfere with subsequent GC/MS quantification of steroids. Some researchers prefer to use HPLC for final purification.[40,70]

Once the steroids and/or steroid conjugates have been extracted from the biological matrix (whether by liquid or solid extraction), an initial separation into steroid classes (if only unconjugated compounds are to be analyzed) or into ''free'' steroids, glucuronides, mono- and di-sulfates may be required. HPLC, capillary GC, and TLC have been widely used in the separation and quantification of androgens as described below.

Using high-performance TLC plates, a complete separation of androgens and their metabolites with methylene chloride–cyclohexane–acetone (70 : 25 : 5, v/v/v) has been reported.[71] Following derivatization of the steroids while still on the plates by cinnamic aldehyde, 4-dimethylaminobenzaldehyde, and sulfuric acid, quantitative determination was achieved by fluorescence.

Since some steroids are difficult to resolve by TLC, special modifications, such as multiple running (using the same system twice or different systems) or two-dimensional TLC, were tried in order to improve separations.[72–75] Appreciable increases in resolution were achieved, but at the sacrifice of speed.

In GC, the use of capillary columns has resulted in improved resolving power over packed columns and has proved invaluable in analyses of extracts of various biological fluids.

In order to increase volatility and improve heat stability in GC, many substances have been used as derivatizing agents. Among these have been the *O*-methyl oximes for derivatization of ketonic functions and the TMS ethers for hydroxyl functions.[76,77] Others have used the oxime instead of the *O*-methyl oxime, coupled with TMS ethers.[78] For hydroxyl group derivatization, alternatives to TMS ethers are the *t*-butyldimethylsilyl (TBDMS) ethers.[69] Other derivatives available for steroid hydroxyl groups are acetates[79] or trifluoroacetates.[80]

7.4 High-performance Liquid Chromatography

The most important uses of HPLC have generally been the separation and measurement of steroids in tissue preparations and perfusates, or synthesized in chemical reactions, and also for analysis of extracts of steroids endogenous to tissues such as the adrenals and testes. Moreover, HPLC has been valuable in the purification of steroid-containing extracts prior to immunoassay, being particularly useful in situations where high-specificity antisera are not available.

Makin and Heftmann[81] have reported on the application of HPLC to the analysis of C_{21}, C_{19}, and C_{18} steroids. The technique has not been used extensively for the quantification of C_{19} steroids in human body fluids, because the majority of detectors normally used with HPLC cannot measure the low concentrations often present. To overcome the problem of the relative insensitivity of UV detection at 240 nm, Payne[82] used specific bacterial hydroxysteroid dehydrogenases for detection and quantification after HPLC separation of serum steroids.

In attempting to improve resolution of steroids or to reduce the overall elution time for a chromatographic run, while still retaining acceptable resolving power, reports of various modifications to HPLC technology, such as using multistep gradient elution and using microbore columns, have been published.[83,84]

7.5 Mass Spectrometry

Coupled with capillary GC or HPLC, MS has been extensively employed in androgen analysis. The techniques used included MS with selected ion monitoring (SIM), metastable peak monitoring, and MS/MS. Fast atom bombardment/mass spectrometry (FAB/MS), after separation by HPLC, has been used in the quantification of intact conjugates without the need for prior hydrolysis.[85]

GC/MS has been useful in studies of metabolism and biosynthesis of androgens.[86,87] Moreover, GC/MS is proven to be a simple analytical screening procedure for the estimation of total androgen conjugates in post-competition urine inspection.[88–89] Hartmann[90] reported that DLs of 0.02–0.1 g kg^{-1} were reached by GC/MS (EI) in the SIM mode. Cairns[91] described the analysis of testosterone esters by MS/MS.

7.6 Immunoassay of Androgens

In addition to its utility for routine analysis of androgens in clinical laboratories, RIA has also been used in analytical and biosynthetic studies in vitro or in vivo.

Separation of the various forms of testosterone has been accomplished by various methods. Older procedures such as equilibrium dialysis (EQD),[92] centrifugal ultrafiltration,[93] and ammonium sulfate precipitation have been modified to increase reproducibility and permit analysis of large numbers of samples.[94]

Since RIA is by nature a heterogeneous technique, the separation of bound and free analyte is necessary for accurate counting. In addition to protein precipitation, DCC has been used extensively, as well as hydroxylapatite.[95] However, these methods prolong the assays and reduce the possibility of automation. Fiet[96] described a technique called scintillation proximity assay (SPA), which eliminates the separation of bound and free steroid in RIA.

Improvements in EIAs, such as enzyme-linked immunosorbent assay (ELISA), for testosterone and other C_{19} steroids, which give greater sensitivity,[97] improved validation, and reduction of non-specific binding, have been published. These improvements have been achieved by the use of various reporter enzymes, such as alkaline phosphatase, HRP,[98] β-galactosidase, and penicillinase.[99]

For FIAs, the most common labels are coumarin derivatives and fluorescein. The disadvantage of these and many other fluorescent compounds is that they give high background signals. In order to resolve this difficulty, time-resolved fluorometry, using the chelates of the lanthanides europium, samarium, and terbium has been developed.[100,101] This method is capable of providing FIAs with sensitivities of 10^{-15}–10^{-16} mol L^{-1}.

8 PROGESTINS

The main clinical use of assays for progestins is determining whether a woman has probably ovulated in a given cycle and if the luteal phase is adequate for pregnancy to be possible. The determination of synthetic progesterones has became important owing to their increasing uses as contraceptive agents. The quantification of neurosteroids (steroids in brain), of which pregnenolone is one of the most important, has evoked intense interest and has been done by RIA, GC/MS, and HPLC.[102,103]

8.1 Identification Tests for Progestins

For pharmaceutically important progestins, IR and UV at 200–400 nm are the most frequently used identification tests specified by the USP 23. In the IR techniques, the potassium bromide pellet method is used.

In the UV technique, the Δ^4-3-keto group is the characteristic chromophoric group in progestins. The conjugation band is fairly intense (λ_{max} 240 nm, $\varepsilon \sim 1.7 \times 10^4$ L mol^{-1} cm^{-1}). The effect of the second double bond at the Δ^6 position is significant, causing about a 40 nm bathochromic and a considerable hyperchromic shift, e.g. megestrol acetate.

In IR spectra, progestins show bands of medium intensity (~1635–1605 cm^{-1}) due to unsaturation as α,β-unsaturated ketones. Together with the carbonyl absorption (1680 cm^{-1}), this is one of the best ways to identify progestins. More detailed correlations of progestin IR bands are available in the literature.[1]

8.2 Assays of Raw Materials and Medicinal Products

Assays of progestins as raw materials and in medicinal products are summarized in Table 6. UV is not only an important detection mode in HPLC, but also is a useful analytical method for identification purposes although it may require suitable derivatization of the analyte.

8.3 Analysis of Progestins in Biological Media

Generally, analysis of progestins in biological material requires extraction of the analyte from the sample, separation into individual components, and their subsequent determination. Although extraction is time-consuming and expensive, it is often necessary because it can increase the specificity and sensitivity of the final assay system by reducing the matrix effect. In some cases, good correlation and agreement between direct and extraction methods have been demonstrated.[104]

The extraction of the progestins from the biological material is dependent on the matrix involved. In some cases, it is necessary to hydrolyze conjugates, e.g. glucuronides and sulfates, with enzymes before extraction. There is usually a compromise on the polarity of the extraction solvent; the less polar extraction reagents will give the lower extraction efficiencies for progesterone but will also reduce interferences from unwanted polar cross-reactants.

Meng[105] reported a method for combined analysis of conjugated progesterone metabolites and bile acids in serum and urine of pregnant women, which put emphasis on extraction and separation. Total neutral steroids were extracted with ODS-bonded silica. Groups of conjugates were separated on the lipophilic ion-exchange triethylaminohydroxypropyl Sephadex LH-20 (TEAP-LH-20). Sequences of hydrolysis/solvolysis and separations on TEAP-LH-20 permitted separate analyses of steroids, glucuronides, monosulfates, and disulfates. Extraction and solvolysis of steroid conjugates were monitored by FAB/MS.

Clouet[106] described the identification of endogenous 19-nortestosterone in pregnant ewes by GC/MS. SPE and liquid–liquid extraction were used in that method. In addition, G60 purification and HPLC purification were used to increase the sensitivity of the final assay.

The quantitative determination of pregnanolone in rat brain was achieved by RPHPLC with fluorescence

Table 6 Methods used in the assay of progestins and oral contraceptives in USP 23

Compound	Method	Detector	Packing	Mobile phase
Progesterone and injection and sterile suspension	HPLC	254 nm	ODS	H_2O–*i*PrOH, 72 : 28
Hydroxyprogesterone caproate	UV	240 nm	–	EtOH
Caproate injection	UV	380 nm	–	Isoniazid Reagent
Megestrol acetate and tablets	HPLC	280 nm	ODS	ACN–H_2O, 55 : 45
Medroxyprogesterone acetate and acetate tablets	HPLC	254 nm	ODS	ACN–H_2O, 40 : 60
Sterile suspension	HPLC	254 nm	Porous silica microparticles	Butyl chloride, hexane and ACN 700 : 300 : 80
Norethindrone	UV	240 nm	–	EtOH
Tablets	UV	380 nm	–	Isoniazid Reagent
Norethindrone and ethinyl E2 tablets	HPLC	200 nm	ODS	ACN–H_2O, 60 : 40
Norethindrone and mestranol tablets	HPLC	200 nm	C_8	ACN–H_2O, %0 : 50
Norgestrel	UV	241 nm	–	EtOH
Tablets	UV	380 nm	–	Isoniazid Reagent
Levonorgestrel	UV	241 nm	–	EtOH

Table 7 Extraction of progestins

Progestin	Solvent (or method)	Sample	Ref.
Progesterone	Diethyl ether	Human plasma	107
Progesterone	Addition of ethanol (10%, v/v), followed by extraction with light petroleum	Human plasma	108
NETA	Basic pH into diethyl ether–dichloromethane (3 : 2, v/v).	Human plasma	109
19-Nortestosterone	SPE, C_{18} column	Urine of ewe	106
Pregnenolone	SPE, Bond Elut C_8 cartridge	Rat brain	103
NET and six metabolites	Extrelut column, pH 5	Human plasma	110
Conjugated progesterone metabolites	ODS-bonded silica	Serum and urine of pregnant women	105

NET, norethisterone; NETA, norethisterone acetate.

detection using 1-anthroyl cyanide as the derivatization reagent and the internal standard method.[103] The desired fraction was obtained from a rat brain with the combined use of a Bond Elut C_8 cartridge for the SPE and lipophilic gel (piperidino-hydroxypropyl Sephadex LH-20) for the ion-exchange chromatography. The achieved DL was 0.2 ppb (initial volume: 20 mL).

These and other common methods for the extraction of progestins are summarized in Table 7.

8.4 Measurement of Progestins

Presently, determination of progestins is mainly performed by immunoassays and less frequently by other methods such as HPLC, GC, and GC/MS. Competitive immunoassays are the principal methods for progestin measurement. A wide variety of labels are used, including ^{125}I, ^{3}H, enzymes, or fluorescent compounds. Separation of the free and bound analyte use methods based on affinity and methods based on coupling of the antibody to some form of solid phase, such as DCC absorption, as well as ammonium sulfate precipitation, and second antibody precipitation.

Use of nonisotope labels has enabled some progestin assays, such as EIA and FIA, to be simplified and made more sensitive. Currently available automated procedures for plasma progesterones utilize a similar principle with a progesterone-peroxidase conjugate.[111] Table 8 shows some examples of immunoassays reported for the analysis of progestins.

8.5 Progestin Analysis by Gas Chromatography

GC was established as the most sensitive method for the measurement of progestin in the 1960s. At that time, the maximum sensitivity was 0.1–0.2 ng mL^{-1}, although specificity was dependent on the efficient separation. Improvements were subsequently made by

Table 8 Immunoassays for progestin

Method	Compounds	Label	Refs.
EIA	NET in plasma and urine	HRP	112
	Plasma progesterone	HRP	113
	Plasma progesterone	Alkaline phosphatase	114
	PG in urine	Lysozyme	115
FIA	PG in urine	Fluorescence	116
RIA	Progesterone in serum	^{3}H	117
	Plasma progesterone	^{3}H, ^{125}I	118, 119
	NET and norgestrel	^{125}I-TME	120
	Cyproterone	^{3}H or ^{125}I	121
	Medroxyprogesterone acetate (MPA)	^{3}H	122
	NET (NE)	^{3}H	123

	Salivary progesterone	–	129

TME, tyrosine methyl ester.

employing more sensitive detection systems, including argon ionization,[130] flame ionization,[131] and electron capture,[132] which used various derivatization reagents including chloroacetate, chlorodifluoroacetate, and hepta-fluorobutyrate in order to increase the sensitivity of electron capture. Lucis[133] has reviewed several GC procedures for the determination of urinary pregnanediol. The methods involved enzymatic hydrolysis, column chromatography on alumina, and separation and quantitation by GC as free steroids or by formation of derivatives.

Pommier developed an analytical method for the determination of NETA in human plasma by capillary GC/MS with testosterone acetate as the internal standard.[109] The compounds were converted into their pentafluoropropionyl derivatives before determination. The GC/MS used a mass selective detector at m/z 486 for NETA. The detection range was 0.10–10 ng mL^{-1}.

Mathur[102] described a GC/MS method for identification and quantification of brain steroids and their conjugates, which includes pregnenolone, 3β-hydroxy-5α-pregnan-20-one, and 3α-hydroxy-5α-pregnan-20-one. The steroids exist as unconjugated compounds and as sulfates, lipoidal esters, and sulfolipids.

Simultaneous determination of NET and six metabolites in human plasma was achieved by capillary GC/MS.[110] The compounds are determined after enzymatic hydrolysis and conversion to bistrimethylsilyl derivatives. The reproducibility and accuracy of the method were found suitable, over the range 0.5–8 ng mL^{-1} for NET and five of the metabolites.

Table 9 summarizes the progress made in the analysis of progestins by GC.

8.6 Progestin Analysis by High-performance Liquid Chromatography

HPLC is an excellent analytical method, but derivatization may be necessary to increase the response of progestins because they are not very responsive to the commonly used detectors. Compounds with poor detector response can be determined using indirect UV or fluorescence detection. In this technique, a UV- or fluorescence-absorbing species is added to the mobile phase and the detection results from the reduction in response of the probe on elution of the sample. RPHPLC is the main mode used in the indirect detection of both charged and uncharged species. In HPLC, β-cyclodextrins have been used either chemically bonded as a stationary phase or added to the mobile phase. It has been postulated that inclusion complexation between the progestin and β-cyclodextrin leads to improved resolution and shorter separation time. Lamparczyk[58] investigated the influence of mobile-phase composition, concentration of β-cyclodextrin, and temperature in the HPLC separation of norgestrel. Enantiomers were detected by using UV detection at 240 nm. The results showed that chiral recognition is maintained at 20 °C, baseline separation is observed at 0 °C, and the best chiral separation was achieved in the range from −5 °C to 0 °C.

The quantitative determination of pregnenolone in rat brain was achieved by RPHPLC with fluorescence detection using 1-anthroyl cyanide as the derivatization reagent and the internal standard method.[103]

Agnus[136] reported the indirect photodetection of pregnanolone by HPLC on a Cyclobond column using UV detection at 280 nm and testosterone as the internal standard. A UV-absorbing species (testosterone) was added to the mobile phase and detection resulted from the perturbation of the distribution equilibrium of the probe on injection of the sample. This method can be used as an alternative for the detection of poorly UV-absorbing species, but both the sample and the marker must interact with β-cyclodextrin.

Gorog[137] described the role of HPLC/diode-array UV spectroscopy in the identification of minor components

Table 9 GC and GC/MS methods for progestin estimation

Progestin	Method	Ref.
Progesterone in serum	GC/Argon ionization	130
Progesterone in serum	GC/Flame ionization	131
Progesterone in serum	GC/Electron capture	132
Pregnanediol in urine	GC	133
Progesterone in saliva	GC/MS, SIM	134
Medroxyprogesterone acetate	GC/MS	135
NETA in human plasma	GC/MS, SIM	109
Endogenous 19-nortestosterone in pregnant ewes	GC/MS, Total ion monitoring and selective ion monitoring	106
Profiles of conjugated progesterone metabolites and bile acids in serum and urine of pregnant women	GC/MS, Total ion monitoring and selective ion monitoring	105
Pregnenolone, 3β-hydroxy-5α-pregnan-20-one, 3α-hydroxy-5α-pregnan-20-one, and their conjugates	GC/MS, selective ion monitoring	102

Table 10 HPLC methods for progestin analysis

Compound	Column	Solvent (v : v)	Detector	Ref.
Hydroxylated impurities of norgestrel	S1 – 10 silica	Chloroform – acetone	Diode-array UV	137
Norgestrel enantiomers	Knauer ODS-1, Supelco ODS	CH_3CN-H_2O, 25 : 75	UV	58
Pregnenolone	J'sphere ODS-18	CH_3CN-H_2O, 15 : 2	Fluorescence	103
Pregnanolone	Cyclobond column	CH_3OH-H_2O, 65 : 35	Indirect UV	136

(impurities, degradation products, metabolites) in various matrices of progestin drug products. Hydroxylated impurities (degradation products) of norgestrel (6α and β, 10β-hydroxyl derivatives) were identified on the basis of their UV spectra and retention time matching with synthesized impurities.

Table 10 summarizes some representative HPLC methods.

9 CONTRACEPTIVES

Since contraceptives contain only estrogens and progestins, the methods for the combinations are similar to those described under previous topics.

Dorantes[138] reported a modification of the USP dissolution method for the analysis of norethindrone and ethinyl E2 tablets. Jiang[139] reported the HPLC analysis of injectable contraceptive preparations containing NET enanthate and E2 valerate.

The separation of seven ethynyl steroids registered as oral contraceptives by micellar electrokinetic chromatography (MEKC) has been described by Poole.[140]

10 CORTICOSTEROIDS

Because of the serious side effects associated with the medicinal use of corticosteroids as anti-inflammatories, many analogs are available and are official in the USP 23. Assays of corticoid raw materials specified in USP are shown in Table 11.

In the search for corticosteroids with improved therapeutic profiles, a great many compounds have been developed that are closely related structurally and have very similar physical properties. These similarities give rise to unique difficulties in accurately analyzing for the corticosteroids in their medicinal products and, more importantly, in biological matrices where their levels are diagnostic for many pathological processes. For these reasons, corticosteroid assays require effective separation techniques, as well as specific and selective detection methods. Since the concentrations in biological matrices are small, sensitivity is also an important requirement in order to lessen estimation error.

Acceptable separation efficiency can be achieved in many cases by simple extraction or back-extraction with suitable solvents. If this is not sufficient, a chromatographic step may be necessary using TLC, paper chromatography, column chromatography, or HPLC. CE has also proven to be a valuable separation modality.[6,141] The last two methods show the most promise for clinical analyses where speed and the potential for automation are important.

Since most of these steroids have acceptable absorptivities, detection can be done efficiently by UV spectroscopy. In more difficult situations, immunoassays, such as RIA, can improve sensitivity. The use of a mass spectral detector after separation by GC or HPLC yields not only sensitivity but also specificity through the use of SIM.

10.1 High-performance Liquid Chromatography

Normal- and reversed-phase HPLC operating in a wide polarity range have been developed for the rapid screening of natural and synthetic corticosteroids The developments in HPLC analysis of corticosteroids for the determination of clinically important steroids in biological specimens have been reviewed.[142,143] Various sample preparation techniques were also described.

Takeda has developed a chemiluminescence high-performance liquid chromatographic method for the determination of corticosteroids and tetrahydrocorticosteroids.[144] Garg[145] described the simultaneous analysis of prednisone, prednisolone, and their major hydroxylated metabolites in urine by HPLC. A rapid HPLC analysis and stability study of hydrocortisone 17-butyrate in cream preparations is described by Wanwimolruk.[146] Chen[147] reported the stereochemical analysis of betamethasone and dexamethasone by derivatization and HPLC.

Table 11 Methods used in the assay of corticoid raw materials in USP

Compound	Method	Detector (nm)	Packing	Mobile phase or solvent
Cortisone acetate and tablets and sterile suspension	HPLC	254	Porous silica	[a]
Desoxycorticosterone acetate and injection and pellets	Visible	525	–	Blue tetrazolium reagent
Hydrocortisone and acetate and hemisuccinate	HPLC	254	Porous silica	[a]
Sodium phosphate	UV	239	–	Alkaline phosphatase and methylene blue
Sodium succinate	Visible	525	–	Blue tetrazolium reagent
Valerate	HPLC	254	ODS, 30–50 μm	ACN–H_2O, 45 : 55
Betamethasone	HPLC	254 or 240	ODS	ACN–H_2O, 37 : 63
Acetate	HPLC	254	ODS	ACN–H_2O–HOAc, 700 : 800 : 63
Benzoate	HPLC	254	ODS	ACN–H_2O, 60 : 40
Dipropionate	HPLC	254	ODS	ACN–H_2O, 50 : 50
Sodium phosphate	HPLC	254	ODS	MeOH–0.05 M K_2HPO_4, 1 : 1
Valerate	HPLC	254	ODS	ACN–H_2O, 60 : 40
Dexamethasone	HPLC	254	ODS	ACN–H_2O, 7 : 3
acetate and sodium phosphate	HPLC	254	Phenyl silica	0.07 M TEA(pH 5.4)–MeOH, 74 : 26
Fluocinolone acetonide	HPLC	254	ODS	H_2O–ACN–THF, 77 : 13 : 10
Fluocinonide	HPLC	254	ODS	ACN–H_2O, 50 : 50
Flumethasone pivalate	Visible	520	–	Blue tetrazolium reagent
Flunisolide	HPLC	254	Octyl silane	H_2O–ACN, 3 : 2
Prednisolone and acetate	HPLC	254	Porous silica	[a]
Hemisuccinate	UV	243	–	EtOH–$CHCl_3$
Sodium phosphate	UV	241	–	Alkaline phosphatase and methylene blue
Tebutate	HPLC	254	Porous silica	Isooctane–THF–EtOH, 89 : 10 : 1
Prednisone	HPLC	254	ODS	H_2O–THF–MeOH, 688 : 250 : 62
Triamcinolone	HPLC	254	ODS	MeOH–H_2O, 60 : 40
Acetonide	HPLC	254	ODS	ACN–H_2O, 30 : 70
Diacetate	HPLC	254	ODS	5 mM K_2HPO_4–ACN–THF, 62 : 37 : 1
Hexacetonide	HPLC	235	Porous silica	Isopropanol–CH_2Cl_2, 3 : 97
Fludrocortisone acetate	Visible	525	–	Blue tetrazolium reagent

[a] Butyl chloride–H_2O saturated butyl chloride–THF–MeOH–HOAc, 95 : 95 : 14 : 7 : 6.

10.2 High-performance Liquid Chromatography/Mass Spectrometry

Render[148] reported the electrospray mass spectrometric characterization of a nonpolar 18-hydroxy-11-deoxycorticosterone dimer. The dimer was purified by HPLC and further analyzed by electrospray MS.

Fiori[149] reported the identification of corticosteroids as illegal feed additives in milk replacers by LC/MS using CI. SPE (C_{18}), C_8 column separation, and data acquisition (positive ions) in the scan range m/z 200–550 were used to differentiate and identify compounds at levels in the range of 20–100 ppb.

10.3 Gas Chromatography/Mass Spectrometry

GC/MS provides excellent sensitivity as well as improved specificity and a number of reports of its use have been published. Several techniques have been described for cortisol using both radiolabeled and stable-isotope dilution methods.[150,151] The technique can also be used for the determination of cortisone in human plasma.[152,153]

10.4 Immunoassay Combined with High-performance Liquid Chromatography and/or Gas Chromatography

Delahaut[154] reported the quantitative determination of several synthetic corticosteroids by GC/MS after purification by immunoaffinity chromatography. Primary extracts from different matrices (liver, milk, urine, and feces) were first purified on C_{18} cartridges. The CI negative ionization mode was used. The estimated detection and quantification limits were, respectively, 0.25 and 0.5 ppb or lower.

In order to increase selectivity of the assay of corticosteroids and simplify the sample pretreatment procedure, Lovgren[155] evaluated MLC using Tween 20 as surfactant preceding immunoassay. It was shown that the separation was dependent on several parameters, such as temperature, the concentration of Tween 20, pH and ionic strength of the mobile phase, and nature of the stationary phase.

10.5 Micellar Electrokinetic Capillary Chromatography

Wiedmer[156] has discussed the successful combination of MEKC with electrospray ionization mass spectrometry (ESIMS) for the analysis of some corticosteroids. Optimization of the surfactant concentration and the length of the injected micellar plug were necessary for efficient analysis.

Bumgarner[157] enhanced separation of corticosteroids by using mixed micelles of short-chain alkyl surfactants and bile salts in electrokinetic chromatography. It was found that separation patterns are mostly influenced by the number of hydroxyl functional groups on the steroidal backbone of the bile salts, while the type of ionic head group has little effect on the steroid separation. And the addition of the short-chain alkylsulfonate sodium butanesulfonate to the mixture of taurocholate and glycodeoxycholate greatly improved the separation of the 17 corticosteroids and provided a baseline separation of all solutes.

Nishi[141] achieved the separation and determination of lipophilic corticosteroids and benzothiazepin analogs by MEKC using bile salts.

11 CARDIAC STEROIDS

Since the medicinal properties of the *Digitalis* species have been known for centuries, there has always been considerable interest in analytical methods. Formerly, the assays in plants and pharmaceutical preparations utilized colorimetric and fluorometric assays. More modern methods are used for the medicinal agents containing the major alkaloids of the *Digitalis* species, digoxin and digitoxin, which are official in the USP. Analyses of these products are all done in a similar manner, by RPHPLC using ODS columns with 3–5 μm packing and UV detection at 218 nm.

Since there is a small margin between therapeutic and toxic concentrations in body fluids, more sensitive methods such as RIA, which was originally developed for digoxin analysis, and fluorescence polarization assay were required. However, HPLC is superior for the separation of digitalis metabolites, which often cannot be differentiated by immunological methods because of considerable cross-reactivity with the antibody. In order to improve sensitivity, the HPLC method is often combined with RIA and fluorescence polarization immunoassay (FPIA) detection. Embree[158] compared digoxin analyses by HPLC/postcolumn derivatization and FPIA.

11.1 Separation and Purification

Ikeda[159] developed an analytical method for the determination of cardiac glycosides in *Digitalis lanata* leaves by RPTLC. The procedure consisted of extraction of dry leaf powder with 50% methanol and cleanup by Sep-Pak cartridges prior to RPTLC analysis on an octadecylsilyl bonded silica gel plate, using a developing solvent of ACN–methanol–0.5 M NaCl (1 : 1 : 1). They also reported a quantitative HPLC method for analysis of cardiac glycosides in *Digitalis purpurea* leaves.[160]

11.2 Immunoassays

Miles[161] described the determination of salivary digoxin with a dry strip immunoassay. Analysis of salivary digoxin using a rapid dry chemistry, enzyme-labeled immunometric assay (ELIA) was compared with FPIA. There were no significant differences found between ELIA and FPIA determinations of salivary digoxin, serum digoxin, or saliva/serum concentration ratios.

Lovgren[162] described the application of new non-competitive flow injection EIAs for determination of digoxigenin. Antibody fragments reacting with digoxigenin and labeled with alkaline phosphatase, were used to convert 4-methyl umbelliferyl phosphate to a fluorescent product measured downstream.

Oosterkamp[12] reported analysis of digoxin and its metabolites by using FIA as an on-line postcolumn detector coupled to HPLC. In a later study, he further discussed different strategies for using this technique.[9]

11.3 High-performance Liquid Chromatography

Belsner[163] developed a postcolumn derivatization method for the fluorescence detection of cardenolides in RPHPLC by fluorescence derivatization of cardiac glycosides with concentrated acids. The column effluent is blended with concentrated acids in a knitted tube reactor, accelerated by Cu(II) acetate or Co(II) nitrate in H_2SO_4. Cardiac glycoside levels of less than 100 pg glycoside in 1 mL of plasma are detectable.

Wolfender[164] studied cardenolide glycosides in crude plant extracts by LC combined with thermospray and continuous-flow FAB/MS.

11.4 Thin-layer Chromatography

Ponder[165] developed a method for the determination of digoxin and related compounds in digoxin drug substance and tablets by using HPTLC. Separation of the three compounds was accomplished on a C_{18} reversed-phase plate using water–methanol–ethyl acetate (50:48:2) as the mobile phase. The analytes were determined by densitometry using absorbance for digoxin and fluorescence for the related compounds.

11.5 Micellar Electrokinetic Chromatography

Debusschere[166] describes the influence of some parameters, such as, concentration of surfactant, pH, and addition of organic modifiers and urea on the resolution of four cardiac glycosides by MEKC. Efficiency was improved with a shorter analysis time.

12 VITAMIN D

Vitamin D exists in two forms, vitamin D_2 (ergocalciferol), which is found in yeast and formed from ergosterol by irradiation, and vitamin D_3 (cholecalciferol), which is found in fish oils and is also formed in animal tissue by irradiation of 7-dehydrocholesterol. These compounds are very similar structurally, each exhibiting an open B ring due to scission of the bond between the 9 and 10 carbons. They have minimal biological activity and are metabolized to 25-hydroxyvitamin D (25-OHD_3), which is more active, and 1,25-dihydroxyvitamin D (1,25-$(OH)_2D_3$), which is still more active. The concentrations of 25-OHD_3 and 1,25-$(OH)_2D_3$ reflect the nutritional state of the individual and, therefore, their quantification becomes important in the diagnosis of patients with calcium and phosphate deficiency.

12.1 United States Pharmacopeia Analysis

The USP 23 contains two alternative assays for the vitamins D, one chemical and one chromatographic (HPLC). Because of the complicated formulations of most vitamin preparations and the instability of vitamin D to air and light, both require extensive cleanup and separation procedures. In the chemical method, the sample is first saponified in alkaline solution, extracted with ether, and passed successively through two glass chromatographic columns, one containing siliceous earth, and the other Fuller's Earth. A color is developed in the purified extract using antimony trichloride–acetyl chloride reagent. Absorbance is measured at 500 and 550 nm.

In the HPLC method, the sample is saponified and extracted, then passed at high pressure first through a reversed-phase cleanup column containing an octyl stationary phase. Then the fraction containing vitamin D is passed through a normal-phase column containing porous silica microparticles. Detection is by UV absorption at 254 nm.

12.2 Gas Chromatography

GC has been used successfully to analyze for vitamins D_2 and D_3. However, the procedure is not without problems. The first of these concerns the formation of the pyro and isopyro forms in which the B ring is closed between the 9 and 10 positions as a result of the high temperature environment in the chromatograph. The isomers can be separated using packed columns of medium polarity. The second problem concerns the polarity of the compounds and their metabolites, which are increasingly hydroxylated and usually require derivatization in order to assure separation and detectability. Silylation of hydroxyl groups and oximation of keto functions are the common methods. Use of GC/MS with these derivatives for the measurement of plasma concentrations has been described for all the major vitamin D metabolites.[167]

12.3 High-performance Liquid Chromatography

HPLC separations are usually monitored by the use of UV detectors, since all vitamin D metabolites have an absorption maximum of 264 nm with molar absorptivities on the order of 18 000. In order to enhance the sensitivity of detection of peaks emerging from an HPLC column, other forms of detection have been investigated and one, using fluorescence detection, provides significant improvement in sensitivity. Vitamin D and its metabolites are not themselves fluorescent and in order to utilize this methodology some precolumn derivatization is required. A number of methods for 25-OHD_3 using the formation of fluorescent triazoline adducts have been described.[168,169] The use of substituted 1,2,4-triazoline-3,5-dione (TAD) as a reagent for the protection of the vitamin D *cis*-triene structure during chemical synthesis or modification has been known for many years.[170]

Masuda[171] reported a highly sensitive HPLC assay method using an electrochemical detector for assays of vitamin D metabolites. The assay involves extracting lipids from plasma with methylene chloride and methanol, purification on Zorbax SIL column with 5.5% (v/v) isopropanol in hexane, and quantification by HPLC coupled to ECD. A coulometric system, composed of the dual electrode analytical cell and a guard cell, was used for electrochemical detection of the eluting compounds. The DL was approximately 50 pg mL^{-1} for 25$(OH)D_3$ and 24,25$(OH)_2D_3$ in plasma.

12.4 Protein Binding Analysis

The majority of binding assays for vitamin D and its metabolites rely on some form of saturation analysis using plasma binding proteins, intracellular receptor proteins, or antibodies as the binding proteins. Two sensitive RIAs have been described.[172,173] A comprehensive list of these methods is given in a number of reviews.[174,175]

12.5 Mass Spectrometry

HPLC can be directly linked to a mass spectrometer (HPLC/MS), and there have been descriptions of the use of thermospray LC with MS for vitamin D metabolites.[176–178] A method for investigating the conjugates of vitamin D_3 using FAB/MS has been described.[179] Litwiller[180] used FAB/MS to prove the existence of a monoglucuronide of 1,25-$(OH)_2D_3$.

13 BILE ACIDS

Bile acids, e.g. cholic acid, are formed in the liver from cholesterol and, therefore, have structural similarities, although they are more highly hydroxylated. They are conjugated in the liver with nitrogenous bases, e.g. glycine and taurine, to yield the bile salts glycocholate and taurocholate. These may also be sulfated and/or glucuronidated. They are excreted into the intestine to emulsify fats for digestion and then reabsorbed and returned to the liver. This process is called enterohepatic recirculation and occurs ten to twelve times a day. Since these processes are so intimately associated with liver and intestinal function, the clinical analysis of bile acids is important in the diagnosis of certain liver or intestinal disorders. Also their assays have been used for probing the complex pathways of cholesterol metabolism.

13.1 Analysis of Bile Acids in Biological Media

Because any biological sample contains a complicated mixture of acids, salts, and conjugated metabolites, efficient extraction from the sample matrix is essential. Since all forms are ionic, the use of an ion-exchange resin such as XAD-2 has been reported to be suitable.[85] SPE cartridges containing octadecylsilyl silica have been used.[40]

Once extracted from their biological matrix, bile acid mixtures may be fractionated into unconjugated, conjugated, sulfated, and glucuronidated moieties. Alme[181] described a method using gel chromatography with Sephadex LH-20, but Setchell[182] found it was first necessary to subject the extract to a cation exchanger to improve separation. Further separation may be achieved using GC or HPLC. Chaplin[183] reported that bile acids and their conjugated forms also may be separated by anion-exchange chromatography in alkaline media (0.9 M sodium acetate, 0.1 M sodium hydroxide, and 15% v/v ACN) on a CarboPac PA-100 column.

13.2 General Methods

The most important techniques currently used to measure bile-acid concentrations include enzymatic, GC, GC/MS, HPLC, HPLC/MS, and capillary zone electrophoresis (CZE). Scalia has reviewed the major chromatographic techniques and combined detection systems for the determination of bile acids.[184]

13.3 Enzymatic Analysis

An enzymatic TLC method used the enzyme 3α-hydroxysteroid dehydrogenase to determine total bile acids with a free 3α-hydroxy group.[185] Since the enzyme does not work with bile acids which are sulfated, glucuronidated, or esterified at the C-3 position, it may be necessary to include a preliminary hydrolysis procedure. It is also a convenient way to distinguish between free and conjugated analytes. Further work indicated that, in order to enhance resolution in the analysis of human bile, it was essential to extract with an anion-exchange resin prior to HPLC. In a similar manner, Kato described an enzymatic determination of serum 3α-sulfated bile acids concentration with bile acid 3α-sulfate sulfohydrolase.[186]

13.4 Gas Chromatography

Even since the development of efficient HPLC procedures for bile acids, CGC has provided an excellent method for bile acid analysis, especially when combined with MS. However, since bile acids found in biological matrices are hydroxylated and conjugated, preliminary treatment is necessary to hydrolyze them and increase their volatility. Hydrolysis can be accomplished in acid solution or by using sulfatase or glucuronidase enzymes. Derivatization involves silylation, methylation, or reduction with $LiAlH_4$ for hydroxyl groups and oximation for keto groups. Street[187] has reported on capillary column GC methods for the determination of major bile acids at very low concentrations in human serum and urine. However, since urinary bile acids are conjugated to a greater extent than serum bile acids, preliminary treatment of the urine is necessary to hydrolyze and derivatize them to increase their volatility. Owing to its ability to achieve greater specificity, GC/MS is a superior method for urinary bile acids.[105,188]

13.5 High-performance Liquid Chromatography

Despite the excellent resolving power of HPLC, bile acids have been difficult to separate because of their structural

similarity and extensive hydroxylation. In addition, bile acids do not have strong UV chromophores detectable at wavelengths higher than 220 nm and they also do not have strong fluorophores. In order to increase resolution and sensitivity, pre- and postcolumn derivatization methods have been developed. Precolumn derivatization procedures included the use of 4-bromoethyl-7-methoxy coumarin,[189] 1-bromoacetylpyrene,[190] 1-anthroyl nitrite,[191] and dansylhydrazones.[192] Cavrini[193] used 2-bromoacetyl-6-methoxynaphthalene as a prechromatographic fluorescent-labeling reagent for the HPLC analysis of bile acids. Guldutuna[194] accomplished a sensitive and precise separation and measurement of commonly occurring free and conjugated bile acids in serum, liver biopsies, bile, gastric juice, and feces using HPLC with fluorescence labeling. Sakakura[195] developed a method for the simultaneous determination of bile acids in rat bile and serum by RPHPLC with post-column enzymatic reaction and fluorescence detection. Without prior fractionation and alkaline hydrolysis, 26 unconjugated or conjugated bile acids were determined. The limits of detection were 1–5 pmol.

Kurosawa[196] reported an analysis of stereoisomeric C_{27}-bile acids by HPLC with fluorescence detection. The method involved the derivatization of the C_{27}-bile acids into fluorescent esters with 3-(4-bromomethylphenyl)-7-diethylaminocoumarin. The separation of the 16 kinds of bile acids containing stereoisomers was carried out using a reversed-phase Inertsil C_8-column by gradient elution. The DLs were about 15 fmol.

Bile salts are all surface-active agents and, as such, their ability to solubilize fats in the intestine depends on their hydrophilic–hydrophobic balance, more commonly called hydrophilic–lipophilic balance (HLB). Scholmerich[197] attempted to correlate HLB with the octanol–water partition coefficient. This can be done either by direct octanol–water partition experiments or by RPHPLC using an octyl (C_8) column. Partition coefficients appear to be influenced strongly by the number of hydroxyl groups present on the sterol nucleus and only weakly by the orientation of the groups. In contrast, capacity factors are very sensitive to differences in orientation of ring hydroxyls.[198]

13.6 Mass Spectrometry

Fast atom bombardment spectrometry has been coupled with collision-induced fragmentation for the analysis of taurine-coupled bile acids.[199] Unconjugated, glycine-conjugated, sulfated, and glucuronidated bile acids are first coupled with taurine by using a carbodiimide reagent. The taurine-conjugated bile acids give more intense spectra than the original parent compounds. MS coupled to HPLC for the analysis of bile acids in biological fluids also has been reported.[200] Warrack[201] described ion spray liquid chromatographic/mass spectrometric characterization of bile acids.

13.7 Capillary Zone Electrophoresis

Yarabe[202] demonstrated that CZE with indirect photometric detection is a viable approach to the separation and identification of free bile acids along with their taurine and glycine derivatives. Various parameters such as pH, organic solvent concentrations, column temperature, and type of chromophore electrolyte were investigated to optimize the electrophoretic separation and to maximize the peak capacity. The quality of separation of bile acids can be dramatically improved by incorporating γ-cyclodextrin (γ-CD) in the running electrolyte. As a result, a CZE separation of all 15 bile acids was possible in approximately 30 min using 5 mM-adenosine 5′-monophosphate, 7 mM γ-CD in 75% (v/v) methanol at pH 7.0 (apparent).

ABBREVIATIONS AND ACRONYMS

ACN	Acetonitrile
BSA	Bovine Serum Albumin
CE	Capillary Electrophoresis
CGC	Capillary Gas Chromatography
CGC/MS	Capillary Gas Chromatography/ Mass Spectrometry
CI	Chemical Ionization
CZE	Capillary Zone Electrophoresis
DCC	Dextran-coated Charcoal
DL	Detection Limit
E1	Estrone
E1-S	Estrone Sulfate
E2	Estradiol
ECD	Electron Capture Detection
EG	Estrone-3-glucuronide
EI	Electron Impact
EIA	Enzyme Immunoassay
ELIA	Enzyme-labeled Immunometric Assay
ELISA	Enzyme-linked Immunosorbent Assay
EQD	Equilibrium Dialysis
ESIMS	Electrospray Ionization Mass Spectrometry
FAB/MS	Fast Atom Bombardment/ Mass Spectrometry
FAB/SIMS	Fast Atom Bombardment/Secondary Ion Mass Spectrometry
FIA	Fluorescence Immunoassay

FPIA	Fluorescence Polarization Immunoassay
GC	Gas Chromatography
GC/ECD	Gas Chromatography/Electron Capture Detection
GC/MS	Gas Chromatography/Mass Spectrometry
GC/NPD	Gas Chromatography/Nitrogen–Phosphorus Detection
HDLC	High-density Lipoprotein Cholestrol
HLB	Hydrophilic–Lipophilic Balance
HPLC	High-performance Liquid Chromatography
HPLC/HPLC	Tandem High-performance Liquid Chromatography
HPTLC	High-performance Thin-layer Chromatography
HRP	Horseradish Peroxidase
IR	Infrared
IRS	Infrared Spectroscopy
LC	Liquid Chromatography
LIF	Laser-induced Fluorescence
MEKC	Micellar Electrokinetic Chromatography
MLC	Micellar Liquid Chromatography
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
NET	Norethisterone
NETA	Norethisterone Acetate
NMR	Nuclear Magnetic Resonance
NPD	Nitrogen–Phosphorus Detection
ODS	Octadecyl Silane
PG	Pregnanediol-3-α-glucuronide
RAD	Receptor Affinity Detection
RIA	Radioimmunoassay
RPHPLC	Reversed-phase High-performance Liquid Chromatography
RPTLC	Reversed-phase Thin-layer Chromatography
RSD	Relative Standard Deviation
SDS	Sodium Dodecyl Sulfate
SFC	Supercritical Fluid Chromatography
SIM	Selected Ion Monitoring
SPA	Scintillation Proximity Assay
SPE	Solid-phase Extraction
TAD	1,2,4-Triazoline-3,5-dione
TBDMS	*t*-Butyldimethylsilyl
THF	Tetrahydrofuran
TID	Thermionic Ionization Detection
TLC	Thin-layer Chromatography
TME	Tyrosine Methyl Ester
TMS	Trimethylsilyl
USP	United States Pharmacopeia
UV	Ultraviolet
UV/VIS	Ultraviolet/Visible
WCOT	Wall-coated Open Tubular
1,25-$(OH)_2D_3$	1,25-Dihydroxyvitamin D
25-OHD_3	25-Hydroxyvitamin D
γ-CD	γ-Cyclodextrin

The area of vibrational spectroscopy encompasses a number of versatile analytical techniques, many of which have been applied successfully to a wide variety of pharmaceutical analyses. While there are many vibrational spectroscopic techniques, some more esoteric or generally applicable than others, this chapter will concentrate on pharmaceutical applications limited to three specific areas: near-infrared (NIR) spectroscopy, mid-infrared (MIR) spectroscopy and Fourier transform Raman spectroscopy (FTRS). The goal of this work is to provide the interested reader with the background necessary to better understand these vibrational spectroscopic techniques and provide an overview of the breadth of applications for these techniques in analyses of pharmaceutical importance. Recently reported applications will be emphasized. The wide variety of sampling methods associated with these techniques will be highlighted throughout. Recent developments which are expected to have an impact on future pharmaceutical applications will also be discussed. Literature and other resources for advanced study are also provided.

1 INTRODUCTION

The many variations and permutations of infrared (IR) and Raman spectroscopies are collectively known as ''vibrational spectroscopy''.[1,2] The unifying feature underlying all of the vibrational spectroscopies is that the effects being measured are related to molecular motion (i.e. stretching or bending of atoms in a molecule, lattice vibrations, etc.). Vibrational spectroscopy, in one form or another, has been exploited to provide both quantitative and qualitative information about pharmaceutically important samples for decades, despite the sometimes complex nature of the spectral data obtained. The purpose of this chapter is to provide the interested reader with a broad overview of the subject area, the background necessary to understand the application of vibrational spectroscopy to samples of pharmaceutical importance, to review representative recent applications and provide a broad array of corresponding references to facilitate more in-depth inquiry.

The first experience which most students in one of the chemically related sciences have with vibrational spectroscopy occurs in an introductory organic chemistry laboratory. The student's first IR spectrum is generally acquired for a solid or liquid sample either synthesized in the laboratory or provided as an ''unknown'' by the instructor. The amount of light absorbed (or transmitted) by the sample in the MIR region of the spectrum is recorded using a suitable instrument after generally limited sample preparation. The student's knowledge of IR spectroscopy is often limited to having learned in class that the wavelengths at which the compound absorbs IR radiation are indicative of the chemical functionalities in the sample. Once a spectrum is acquired the student is directed to one of the many IR wavelength versus functionality correlation charts found in textbooks. Depending on the number and type of functionalities in the sample, the complex spectral pattern obtained can prove to be overwhelming to the student. Using both positive information (the sample absorbs light in a region indicative of a given functionality) and negative information (the sample does not absorb in the region indicative of another functionality), the student completes his/her first experience in vibrational spectroscopy by listing those functionalities which are probably present in the sample and those functionalities which are probably absent. Another common approach taken by students to determine the likely identity of the sample, or at least to narrow down the possibilities, is to manually compare the spectral data obtained with the spectra contained in a collection of spectra, either on paper or computer readable format. Thus, the concepts of spectral interpretation and spectral matching are also

usually part of the student's introduction to vibrational spectroscopy. The training for most nonchemistry and many chemistry students at both the undergraduate and graduate levels will not include in-depth discussions of other types of vibrational spectroscopy (i.e. NIR, Raman), more complex sample and data-handling techniques or general discussions of other than routine applications of vibrational spectroscopy to structure identification.

The unifying characteristic of all of the types of spectroscopy that come under the general heading of vibrational spectroscopy is that they measure the effect that electromagnetic radiation has on the molecular vibrations of the sample. The reader is cautioned, however, that one of the confusing aspects of vibrational spectroscopy is that different units, i.e. either wavenumbers (cm^{-1}) or wavelength (μm, nm), are used by practitioners of the various methods. The most common units in current use are presented here for comparison.

The energies required to induce transitions between vibrational levels range from the low-energy photons of the far infrared (FIR) (10–200 cm^{-1} or 1000–50 μm), to the moderate-energy photons of the MIR region (200–4000 cm^{-1} or 50–2.5 μm), to the higher-energy photons of the NIR region (14 300–4000 cm^{-1} or 0.7–2.5 μm or 700–2500 nm). It is worth noting at this point that most MIR instruments have an upper limit which extends beyond 4000 cm^{-1} but have a lower limit of 400 cm^{-1}. Low-energy FIR photons are used to probe the low-energy transitions of the sample, for example the lattice vibrations of a polymer. MIR photons are sufficiently energetic to promote changes from the ground vibrational energy level to the first excited state energy levels for the fundamental vibrations of the molecule, and it is for this reason that MIR spectroscopy is useful for functional group analysis. The more energetic NIR photons promote transitions from the ground state to higher than the first vibrational excited state (i.e. overtones). These photons are also capable of interacting with higher vibrational energy states of the molecule, which are combinations of the fundamental frequencies.

While the difference in energy between vibrational states is important for determining which wavelengths and in which region of the spectrum an absorption will occur, the magnitude of the light absorbed is directly related to the probability of a photon being absorbed by the molecule. If the probability is high that a given photon will be absorbed, then the absorbance measured will be high. For fundamental reasons, the probability of an NIR photon being absorbed by a molecule is far less than the probability of an MIR photon being absorbed. For this reason, to obtain a spectrum of a sample in the MIR region requires fewer molecules to interact with the light than in the NIR region. The molar absorptivity (ε) of a compound is a measure of the probability of a photon being absorbed. Molar absorptivities are generally lower in the NIR than in MIR region of the spectrum. This physical observation results in both advantages and disadvantages for these particular forms of spectroscopy which will be discussed in more detail using appropriate applications.

MIR and NIR spectroscopic techniques expose the sample to photons having a range of energies, some of which correspond exactly to the energy level transitions in the molecules of the sample. When the energy of the photon matches an energy level difference of the molecule, the photon may be absorbed, while photons having energies which do not match exactly an energy level of the molecule will not be absorbed. Thus, the energy levels of the molecule can be viewed as being probed directly when performing MIR and NIR absorption spectroscopy. The many forms of Raman spectroscopy are unique among the vibrational spectroscopic techniques in that they are not based on the absorption of a photon, but instead on the inelastic scattering of a photon by the molecules of the sample. The excitation photons used in Raman methods are not absorbed by the molecules of the sample and do not exactly match an energy level difference of the sample molecules. Instead Raman spectra are acquired by measuring the differences in energy between that of the monochromatic excitation photons and the photons scattered by the sample, this difference termed the "Raman shift" and is usually plotted in cm^{-1}.

The simplest way to get a feeling for Raman scattering is to invoke the presence of a "virtual" state. Unlike the energy levels of a molecule which are real, a virtual state is not a real energy state of the molecule, which means that the molecule will not exist in that state for any appreciable time. It is easiest to think of the virtual state as the energy through which the molecule passes in its transition between its initial interaction with the excitation photon and the energy that it will have at the point at which a photon is scattered. Figure 1 presents a simplified vibrational energy level diagram for a molecule having a

Figure 1 Schematic diagrams indicating energy level transitions for Rayleigh scattering, Stokes Raman scattering and anti-Stokes Raman scattering.

ground state and an excited state as well as a schematic description of the scattering processes. For this simplified example, at the time when the molecule is exposed to the incident photon, it can be in either the ground or excited vibrational energy level. If the molecule interacts with the incident photon and returns to the same energy level as it started, then the scattered photon will be of the same energy as the incident photon. This phenomenon is an ''elastic'' scattering process known as Rayleigh scattering. Raman scattering occurs when the initial and final energy states of the molecule are different after interacting with the incident photon. Most of the molecules of the sample will initially be in the ground vibrational energy level. Interaction with the incident photon can result in the molecule being promoted to a vibrationally excited state. The Raman scattered photon which results from this interaction will have less energy than the excitation photon, with the difference being the energy between the ground and excited states for the molecule. If the molecule in our example is initially vibrationally excited and goes to the ground vibrational state after interaction with the incident photon, then the Raman scattered photon will be of higher energy than the incident photon and thus be Raman shifted to a shorter wavelength. Since the energy difference between the excited and ground states determines the difference in energy between the incident and scattered photon, the Raman shift observed is the same for both the Stokes (Raman shifted to longer wavelength) and anti-Stokes (Raman shifted to shorter wavelength) bands. Stokes bands will, however, be more intense since there is a higher probability of the sample molecules being in the ground state when they interact with the incident photon. It should be emphasized that the overall likelihood of an incident photon being Raman scattered is very small. The vast majority of scattered photons will be Rayleigh not Raman scattered. Thus, it is critical in developing Raman instrumentation to separate the Raman scattered photons from the Rayleigh scattered photons and, in the design of the experiment, to prevent other sources of sample emission, such as fluorescence, from obscuring the weak Raman signal.

Although Raman and IR spectral data are similar in many aspects, there are many theoretical and practical differences between Raman spectroscopy and MIR (or NIR) spectroscopy. For example, the so-called selection rules, which indicate if a given transition will be active, and therefore is likely to be observed, or inactive, and therefore not likely to be observed, are different for the Raman scattering and IR absorption processes. Similarly, water, which strongly absorbs in both the MIR and NIR, is a weak Raman scatterer. Thus, water is not considered a good solvent for obtaining routine MIR spectra of dissolved analytes but is a very good solvent for obtaining Raman spectra of dissolved species. Glass, which has strong bands in the MIR region and therefore, not used for IR sampling, is a weak Raman scatterer, which is one of the reasons glass capillary tubes are often used for Raman sample holders. It is also experimentally easier to obtain Raman spectroscopic data for low-energy transitions (less than 400 cm^{-1}) than by IR spectroscopic techniques.

One of the experimental variables in Raman spectroscopy is the frequency of the incident photons. The intensity of Raman scattering increases in proportion to ν^4, which is the reason that conventional Raman spectra are acquired using visible (VIS) and ultraviolet (UV) laser sources.[3] Unfortunately, UV and VIS photons also are capable of promoting fluorescence either by the analyte or by impurities in the sample. Fluorescence is especially problematic even for the analysis of nonfluorescent analytes in real-world samples since the presence of small amounts of fluorescent impurities can provide sufficient background to obscure the photons due to the weaker Raman scattering. One approach to overcoming fluorescence induced by the incident radiation is to use lower frequency, NIR photons, which are not sufficiently energetic to promote fluorescence for most commonly encountered elements and compounds. The all important decrease in Raman scattering when using NIR incident photons is complicated further by the need to use different detectors than are used for detecting VIS and UV photons. The ability to largely overcome inherent problems with sample fluorescence experienced by conventional Raman spectroscopic techniques have justified the design and development, and has resulted in the commercial availability, of Fourier transform (FT) Raman instrumentation incorporating NIR neodymium : yttrium aluminum garnet (Nd : YAG) lasers. Owing to the higher laser powers generally utilized in FTRS and the reduced intensity of Raman scattering, it should be noted that significant advantages may be gained by using conventional, dispersive Raman spectroscopy to analyze pharmaceutical samples which do not fluoresce.

2 INSTRUMENTAL CONSIDERATIONS

Two distinct types of instruments are used to acquire spectral data in the MIR and NIR regions of the spectrum.[3–5] To understand the difference, it is important to remember that the detectors for these regions of the spectrum are not capable of simultaneously distinguishing between different wavelengths of light. Thus one approach to acquire spectra is to separate the light into discrete wavelengths and allow only photons with a single, known wavelength to reach the detector at any time. This type of instrument often contains a grating to disperse the light, which is why they are classified as ''dispersive'' instruments. It

is important to note that for this type of instrument, at any given moment, most of the light from the source is not reaching the detector, is not providing information, and is, therefore, effectively wasted. Many instruments, especially those used in the NIR for process measurements, utilize optical filters, instead of gratings, to select the wavelength reaching the detector at any given time, but the same principles apply.

An alternative approach can be used for obtaining intensity versus wavelength data using a detector, which is not capable of distinguishing individual wavelengths. In this approach, all wavelengths are allowed to reach the detector at the same time; however, each wavelength in the spectral range is uniquely encoded. Thus, although the detector measures the combined intensity for all of the encoded wavelengths at a given time, suitable decoding provides information on the intensity at any given wavelength. This encoding–measuring–decoding approach is employed in the FT instruments used to obtain MIR, NIR and FT Raman spectra. The most common approach to encoding the IR light is the use of a Michaelson interferometer containing a moving mirror. The light exiting from the interferometer is encoded uniquely at any given point in the mirror's travel. An entire IR spectrum is acquired with each complete sweep of the mirror.

Several advantages which FT instruments demonstrate over dispersive instruments are often listed.[3,6] The most common are the stray light advantage, the throughput advantage, and the multiplex advantage. The stray light advantage arises since only light encoded or modulated by the interferometer provides information. Stray light which is not modulated but reaches the detector does not interfere with the measurement. The throughput advantage, which practically may be more significant for an FT Raman experiment than a Fourier transform infrared (FTIR) experiment, simply stated is that more light from the source impinges on the detector at any given time compared with using a dispersive spectrometer. Clearly, at any given time in a dispersive spectrometer, only a small amount of the source radiation is allowed to reach the detector with most of the source's radiation providing no information. The multiplex advantage is simply that all wavelengths of light are measured simultaneously when using either an FTIR or FT Raman instrument. Another advantage gained when using these types of instruments is that there is an internal laser standard which ensures the wavelength accuracy of the spectral data obtained. It should be noted that the actual importance of these and other so-called advantages for the user's particular application must be individually assessed.

Many of the advances in vibrational spectroscopic techniques and the types of applications that are now possible are due to the vast computational capabilities, which are provided with all FT instruments and available for virtually all other vibrational spectroscopic instrumentation. Advances in computational resources (speed, memory, data storage, and display) have influenced greatly the development and expanded the areas of potential application for vibrational spectroscopic techniques over the past 20 years. In many cases, advanced spectral data-processing techniques have been used to overcome inherent instrumental limitations and difficulties in sampling, compensate for experimental variability and reduce the complexity of the spectral data obtained.

As probably expected, there is generally a high degree of similarity between most vibrational spectroscopic instruments of a given type, even among vendors. Examples of instrument layouts and components along with general descriptions of laboratory and process instrumentation can be found in most undergraduate instrumental methods of analysis texts,[3,4] vibrational spectroscopy monographs,[2,6] and other texts on analytical instrumentation.[5,7] Rapid developments, especially advances in specific components such as optical detectors, can be incorporated very quickly in commercially available instrumentation. The value of information provided on instrument vendor websites, especially concerning current instrument design and specifications should not be underestimated.[8]

Advances in instrumentation and computational capabilities suggest re-evaluations may be prudent for analyses deemed too difficult to perform only a few years ago.

3 SAMPLING

One of the advantages of vibrational spectroscopy is the wide variety of sampling options available.[2–4,6] Spectroscopic data can be acquired for almost any type of sample, often with little or no sample preparation. Minimizing sample preparation is often of paramount importance, not only to reduce analysis time but also to reduce the possibility of changing the sample or introducing impurities during the process. Generally, gaseous, liquid and solid samples can be analyzed using appropriate sampling techniques. With experience, samples that are otherwise thought not to be appropriate for analysis by vibrational spectroscopy, can be analyzed with the appropriate choice of sampling technique.

When choosing a sampling technique where the amount of light absorbed is to be measured (Figure 2), it is important to remember the relationship known as Beer's law shown in Equation (1)

$$A = -\log\left(\frac{I}{I_o}\right. = \varepsilon bc \qquad (1)$$

Figure 2 Schematic diagram for a typical transmission measurement. I_o is the intensity of light impinging on the sample at a given wavelength. I is the intensity of light at that wavelength after passing through the sample.

where A is the absorbance, I_o is the intensity of the incident light at a given wavelength, I is the intensity of the light at that wavelength after passing through the sample, ε is the molar absorptivity in units of liter-moles per centimeter, b is the pathlength or thickness of the sample in centimeters and c is the concentration of the analayte in moles per liter. The molar absorptivity for a given analyte varies with wavelength and spectroscopic region. It is generally observed that molar absorptivity decrease significantly in going from the UV/VIS to the MIR and NIR regions for analytes which absorb in these regions. Thus, to acquire NIR spectra, higher analyte concentrations and longer pathlengths are generally necessary than when obtaining MIR spectra. Although this may at first been seen as a disadvantage for NIR spectroscopy, it will be shown that the ability to use a longer pathlength is often considered one of the advantages of NIR for industrial applications.

The physical state of the sample often suggests the sampling technique to use. MIR spectroscopic data can be acquired for solid samples in many ways. One of the most common sampling techniques is the alkali halide or, as generally practiced, potassium bromide (KBr) pellet technique. KBr is used since it does not absorb in the MIR region and also because it cold flows when pressure is applied. Simply, the solid sample is ground to a powder, which is then mixed with spectral grade KBr powder. The mixture is placed in a special die set and sufficient pressure is applied to cause the KBr to cold flow, forming a KBr pellet, often contained in a metal collar which is part of the die set. The collar containing the pellet is placed in the instrument and an absorbance spectrum is acquired. The ratio of sample to KBr used and the thickness of the KBr pellet formed can be adjusted to obtain the desired level of analyte absorbance. Performing a quantitative analysis using the alkali halide technique can be challenging due to difficulties in preparing reproducible and representative samples.

A similar technique, often used by synthetic chemists to obtain qualitative information, is to prepare what is known as a ''mull''. The solid sample is ground to a powder and dispersed in a few drops of mineral oil. This mixture is applied to a KBr or NaCl optical window and the absorbance spectrum for the mixture is obtained. Since mineral oil contains carbon–hydrogen and carbon–carbon bonds, which absorb in the MIR, regions of the spectrum containing such absorption are not utilized. To obtain spectral information for regions of the spectrum obscured by the bands of the mineral oil, a different mulling agent, generally a perfluorinated oil, is used. The perfluorinated oil absorbs in the region for carbon–carbon and carbon–fluorine bonds but provides the spectral regions not available with a mineral oil mull. Whenever preparing a mull or an alkali halide pellet, it is prudent to remember that potential chemical and/or physical changes may result from grinding the sample.

Another common way to obtain spectra of solids is attenuated total reflectance (ATR).[9,10] Sampling by ATR is demonstrated diagrammatically in Figure 3. ATR sampling utilizes an optical element, which is made from a material having a high refractive index, for example zinc selenide, germanium, or diamond. Sampling is based on the principle that as light passes through a material with a high refractive index, an evanescent wave propagates at the surface of the material in contact with a medium having a lower refractive index. The evanescent wave penetrates into this lower refractive index medium for some distance. The intensity of the evanescent wave decreases exponentially with distance away from the element. If the contacting medium, which in this case is the sample, absorbs light at a particular wavelength, then a decrease in the intensity of light at this wavelength emerging from the ATR element will be observed. The depth of penetration of the evanescent wave depends on the refractive indices of the ATR element, the contacting medium (generally air or the sample) and the angle of

Figure 3 Schematic diagram of sampling by ATR indicating the lightpath and sample arrangement. I_o is the intensity of light impinging on the ATR element at a given wavelength. I is the intensity of light at that wavelength emerging from the ATR element.

incidence of the light on the ATR element. The depth of penetration is wavelength dependent and generally is found to be something between a fraction of a wavelength to several wavelengths in magnitude. The number of reflections in the ATR element can be adjusted by changing the thickness of the ATR element, the length of the ATR element or the angle of incidence of the light entering the element.

Since the depth of penetration of the evanescent wave into the adjacent medium is generally small, the sample must be in intimate contact with the ATR element. Samples which are soft can be pressed on to the ATR element to achieve such contact usually without damaging the element. Care must be taken not to damage ATR elements made from soft materials when pressing hard solid samples or powders into such elements. Likewise, care must be taken not to crack and break ATR elements made from brittle materials when pressing the sample on to the surface. This is especially true when obtaining data for hard samples which are not flat. Thus, in addition to spectroscopic concerns (depth of penetration, wavelength cutoffs and regions of absorption) the type of sample also determines the material from which the ATR element is made. Since the sample is in intimate contact with the ATR element, the chemical reactivity of the sample and the ATR element must also be taken into account.

Another sampling method for obtaining spectra of solids is diffuse reflectance (Figure 4). Diffuse reflectance spectra are obtained by directing light on to a sample and collecting the light that is reflected, diffusely, not specularly, from the sample. The amount of light at the wavelengths which the sample absorbs will be reduced in the diffusely reflected light. Thus, to obtain a spectrum, similar to an absorption spectrum, the diffusely reflected light collected from a sample is ratioed to the light diffusely reflected from a standard. Solid samples are often diluted with potassium chloride and ground to a powder, especially when obtaining a MIR spectrum. The diffuse reflectance technique is widely use for obtaining NIR spectra, often with no sample preparation required.

Figure 4 Schematic diagram for typical diffuse reflection measurement. I_o is the intensity of light impinging on the sample at a given wavelength. I_{dr} is the intensity of light at that wavelength after being diffusely reflected by the sample.

Spectra for liquid samples can be acquired using several sampling techniques. Transmission spectra can be acquired with the use of windows, which are transparent in the IR region of interest. The choice of the window material is made based, not only on the spectral region required for the analysis, but also on the chemical reactivity and solubility of the window material. The most common MIR transmitting materials used for this purpose are potassium bromide (KBr) and sodium chloride (NaCl). Both are water soluble, thus eliminating their use with aqueous solutions or even nonaqueous solutions containing water as an impurity. The lower wavenumber cutoff is $675\,cm^{-1}$ and $400\,cm^{-1}$ for NaCl and KBr respectively. Nonwater-soluble MIR windows, for example calcium fluoride and barium fluoride, are also readily available.

For nonvolatile solvents where maintaining the pathlength is not critical, spectra can be acquired by simply placing a drop of the liquid between two IR transmitting windows. Liquid cells generally use spacers to maintain a given pathlength and are often used if quantitative data are to be obtained. One concern in obtaining spectra for analytes in solution is the absorbance profile of the solvent. The primary concern is that the solvent may absorb strongly in the region of the spectrum where the analyte absorbs, thereby making it difficult if not impossible to obtain spectral information for the analyte. Water is a particularly difficult solvent for IR spectroscopy since it absorbs strongly in the MIR region of the spectrum, especially in the $1600\,cm^{-1}$ and $3000\,cm^{-1}$ regions of the spectrum. To obtain IR spectra of aqueous solutions, very short pathlengths (i.e. $6\,\mu m$) must be used. The choice of solvent and concentration of analyte in the sample dictates the pathlength used for the analysis. Flow cells are also available.

Liquid samples can also be analyzed using ATR techniques. Many types of ATR liquid probes are commercially available. Additionally, there are many different designs for liquid ATR cells which are available commercially, ranging from a simple-to-use trough design, where the liquid in contact with the ATR element is contained in a trough, to more elaborate ATR liquid flow cells. As mentioned above, the depth of penetration in the ATR experiment is determined by several factors, including the refractive index of the ATR element, the refractive index of the sample, which is a liquid in this case, and the angle of incidence of the light. Liquid ATR cells are normally

designed such that the actual thickness of the sample in contact with the ATR element is much greater than the depth of penetration, with the only limit being the amount of sample available. Thus, ATR sampling may prove to be experimentally easier when obtaining spectra of viscous samples or samples which absorb strongly and would require, therefore, very short pathlengths to obtain useful transmission spectra.

Spectra can also be obtained for gas phase samples using appropriate sampling devices. The lower analyte concentrations of gaseous samples requires the use of much longer pathlengths than are used with liquid samples, often several centimeters to several meters. Transmission cells can be constructed from inert materials, such as glass or stainless steel with appropriately chosen IR transmitting windows positioned in the light path to allow the light to pass through the sample.

Similar sampling devices are used for acquiring MIR and NIR spectra, although the lower molar absorptivities for analytes in the NIR region lead to some differences. The lower molar absorptivities allow longer pathlengths to be used for NIR transmission experiments and, as mentioned above, diffuse reflectance spectra can usually be acquired without diluting or grinding the sample. The virtual elimination of sample preparation is a major advantage of NIR spectroscopy. Fiber optic probes are more widely used in NIR than MIR sampling.[11]

Sampling is usually more straightforward for acquiring FT Raman spectra. The goal is to present the sample in such a way that light from the excitation laser impinges on the sample and the Raman scattered radiation is directed to the collection optics. Sampling is further simplified by the fact that glass is a weak Raman scatterer and a reasonable window material in the NIR region of the spectrum. Thus, glass nuclear magnetic resonance (NMR) tubes and melting point capillary tubes make economical sample containers for obtaining FT Raman spectra of either liquids or powdered solid samples. Caution must be exercised however in the choice of glass tube in that some glasses contain impurities or constituents that fluoresce when exposed to the NIR excitation from the laser source. An intense fluorescence background can obscure the weaker Raman bands. Another sampling concern when obtaining Raman spectra is that the sample can be degraded by the intense laser radiation. Likewise, temperature-dependent changes in the spectra may be observed due to heating of the sample by the laser. Rotating the sample so that the same spot is not constantly in the laser focus and externally cooling the sample are options for overcoming these problems. FT Raman spectra can also be acquired for solid samples with design of an appropriate sample holder. It should be noted obtaining representative spectral data for large samples may be a concern because of the small area irradiated by the laser.

4 MICROSAMPLING AND MICROSCOPY

Microsampling and microscopic imaging, both IR and Raman, are areas of vibrational spectroscopy which have undergone major advances in the past 10 years. Although these techniques are often classified as being distinct from vibrational spectroscopic techniques using macroscopic sampling, it could be rationalized that these imaging techniques are simply extensions of microsampling with unique and powerful advantages. Interfacing a microscope to an IR or Raman instrument provides the opportunity to obtain spectral information for microsamples, often called microspectroscopy, and to obtain vibrational spectroscopic images.[12–16]

The power of the microimaging techniques lies in their ability to provide spatial images for specific frequencies within the MIR wavenumber range. Since the frequencies of absorption in this range are correlated with known chemical functionalities, functionality mapping can easily be provided within the spatial resolution of the instruments. The limiting spatial resolution for IR imaging is typically in the range of 5–10 μm, which, while not high by optical imaging standards, is a limitation often overcome by the quality and quantity of spectral data obtained. The spectral resolution reported is typically $4\,cm^{-1}$. Spectra can be acquired for samples either by transmission or reflection.

Many approaches have been taken to develop microsampling/microimaging instruments. One approach is to interface a microscope suitably modified to contain optics for the spectral region of interest with a conventional scanning FTIR instrument. This type of instrument uses a single IR detector element. Spectral data are acquired for one position of the sample at any given time. Clearly this instrumental arrangement can be utilized to obtain IR spectra of small samples, which is really better termed microspectroscopy rather than imaging. To obtain an IR image of a sample, the sample stage is moved a precise distance between data acquisition for adjacent points.[13] The scientific literature contains many elegant studies performed using this rather mechanical approach to IR imaging, which although time-consuming has been practiced for many years and is representative of most of the IR microscopic imaging systems in use today. Recently, IR array detectors have become available. The availability of these detectors is likely to revolutionize the use of IR imaging in the laboratory, assuming the cost for these instruments eventually reaches a level which makes them available to reasonably well equipped laboratories.

One recent development in IR microscopic imaging systems is the combination of a step scan FTIR instrument with a suitably modified microscope containing IR optics and an IR array detector, typically a 64×64 array of mercury cadmium telluride (MCT) elements.[15,16] To understand how this instrument obtains IR spectra, it is necessary to review how a conventional scanning FTIR works. When using a continuously scanning interferometer and a single detector, as is common in laboratory instruments, with or without a microscope attachment, a complete IR spectrum is obtained each time the moving mirror of the interferometer makes a complete scan. The detector simply measures the intensity of the IR radiation falling on it at discrete times (i.e. distances moved by the mirror) as the mirror makes a continuous scan. This approach works well for a single detector element, but does not work if the data acquired from multiple elements (i.e. 4096 elements in a 64×64 MCT array) must be acquired and saved before moving on to the next data acquisition position of the mirror. To overcome this problem, the interferometer is changed from one that acquires data by making a continuous scan to one that has a mirror which stops and acquires data for each appropriate position in the mirror travel. Thus, although each full scan produces a complete interferogram, each point of the interferogram is acquired by stopping the mirror, collecting the IR intensity impinging on each element of the array, and saving these data before proceeding to the next mirror position where the process is repeated. Clearly advances in this instrumentation are likely to be made as larger, faster detector arrays and associated electronics become available in the future.

Applications and issues in microspectroscopy, with special emphasis placed on determining the types of particles of particular interest to people working with pharmaceuticals have been covered extensively by Aldrich and Smith.[12] They provide an appendix listing many sources of particulates commonly found in pharmaceuticals. They also describe general approaches, methods and problems encountered in identifying particulate matter and show how IR microspectroscopy can provide information which complements or confirms the information obtained using other techniques. Applications of IR microimaging in several fields, including minerals, biological materials and semiconductor materials have been reviewed by Krishnan et al.[13] and others.[16] While not applications of pharmaceuticals directly, the examples provided demonstrate the broad applicability of the technique. Owing to the recent developments in array technology and the limited availability and high cost of the latest versions of the FTIR imaging instruments, references to their use for solving pharmaceutical problems are limited. Still it is not hard to imagine, based on the applications already in the literature, that the impact of this new technology and likely improvements in hardware, software, and pricing will result in the use of such systems for solving pharmaceutical problems. An interesting hybrid sampling technique which has recently become available combines the features of ATR and microscopy. Using this technique the sample being analyzed is visually imaged through the ATR element, thus allowing the scientist to see the region being sampled by the element. This micro-ATR sampling technique, using a diamond-tipped ATR element, has been reviewed by Coates and Reffner.[17] As pointed out by these authors, the development of FTIR instruments has greatly increased the opportunity for using sampling techniques where energy throughput considerations were limiting for the older dispersive IR instruments, such as ATR and microsampling applications. Another development has been the introduction of diamond surface ATR elements.[17] Clearly, the use of diamond in addition to providing mechanical advantages also provides more chemical compatibility than many of the other high-refractive-index materials commonly used as ATR elements. (MIR diamond ATR devices are available and have been used for process analysis applications.[18]) Owing to the high cost of diamond, diamond-tipped ATR elements have been used for microsampling. For these devices, the area sampled is approximately 1–2 mm in diameter. The light absorbed by the diamond could interfere with an analysis, but this effect is limited by the small pathlength of diamond through which the IR light must travel owing to the limited thickness of the diamond coating and the limited number of ATR reflections (i.e. 1) in the diamond material.

The ability to visually observe the area being sampled by viewing through the ATR element clearly has merit. A sampling device employing a diamond, micro-ATR element and a charge-coupled device camera which allows such sample viewing has been developed and has recently became commercially available. Coates and Reffner[17] present several applications as examples of sampling using this device, including the analysis of ink printed on a business card, the analysis of several layers of a fiber-optic cable, and the analysis of hair. This approach to IR sampling may prove to be a practical and possibly lower-cost alternative to IR microscopy for routine analysis of at least some types of samples.

5 APPLICATIONS

5.1 Mid-infrared

Pharmaceutical applications of MIR spectroscopy have been published for decades, but the commercial availability of lower-cost FTIR instruments has greatly increased

the range of applications and data processing possible. One area of application which has received a great deal of attention in the literature is the analysis of polymorphs. Several selected examples of polymorph analysis are presented here. For additional references and background the reader is directed to one of the several excellent reviews published.[19,20]

Hartauer et al.[21] described the quantitative analysis of polymorphs of the antibiotic sulfamethoxazole with diffuse reflectance FTIR utilizing the partial least squares (PLS) method for data analysis. The use of diffuse reflectance instead of the KBr pellet or mull techniques is highlighted because of advances in the signal-to-noise ratio obtained with commercially available diffuse reflectance infrared Fourier transform (DRIFT) accessories. Data are collected for light, which is diffusely, not specularly reflected, by the material of interest, which is usually dispersed in a nonabsorbing matrix such as potassium chloride. The authors point out that to obtain quantitative information from the reflectance data obtained, the Kubelka–Munk relationship is employed. This relationship produces a linear relationship between the Kubelka–Munk intensity and the concentration of scattering species, although there are several assumptions inherent in the use of this relationship. The scattering coefficient for the material of interest must be constant, and the light reaching the detector must be diffusely, not specularly, reflected from the sample. As emphasized by the authors, there are several experimental variables which need to be monitored to control the amount of specularly reflected light and the scattering coefficient of the material. Among these variables are some which can be controlled by sample preparation, including the particle size of the scattering material, the packing density, and the homogeneity of the sample, as well as the optical design of the diffuse reflectance accessory used. Fitting the overlapping peaks of the spectra obtained for appropriate calibration standards using the PLS regression approach allowed the concentration of each polymorphic form in an unknown sample to be calculated. For calibration, pure samples of the two sulfamethoxazole polymorphs were prepared and characterized. Sample preparation included grinding the samples to obtain a more homogeneous particle size, although sieving would have been employed if grinding was found to affect the polymorphs. The ground samples were then vigorously mixed with micronized KCl powder, which had a particle size of 1–10 μm. The mixed powder was then placed in a sample cup and compacted using a 2-kg weight. The importance of using a reproducible sample method was stressed. It was noted that significantly sharper spectral bands were obtained for the polymorph which had been ground. Experiments were performed to check the linearity of the Kubelka–Munk intensity with concentration. At lower concentrations of the polymorphs (i.e. less than 2% in KCl) good linearity was observed for several of the less intense bands of each of the polymorphs, but the authors caution that intense bands in the spectra do not demonstrate such linearity, possibly because of increases in specular reflection with increased absorptivity at a given wavelength. Using PLS methods to analyze the data for several calibration standards provided average absolute errors between the actual and predicted values of 0.006% and 0.004% for the two polymorphs of sulfamethoxazole, given as a percentage of the each of the polymorphs in KCl.

Previously, Deeley et al.[22] compared FTRS with NIR excitation to FTIR spectroscopy for analyzing binary mixtures containing two of the five polymorphs of cortisone acetate. The polymorphs of this compound are known to be insensitive to grinding, thus grinding can be used to prepare homogeneous mixtures of the polymorph standards. Both FT Raman and FTIR spectra were recorded for this study using the same optical bench. One potential advantage of FTRS is that no sample preparation is required for powdered samples, although often minimal sample preparation is required for diffuse reflection FTIR measurements. One of the concerns in Raman spectroscopy is the amount of excitation laser power to use for the measurement. Increasing the excitation power of the laser increases the Raman scattering of the sample, but also may thermally damage the sample or increase the number of photons due to fluorescence by the sample or impurities. For this study, excitation powers ranging from 125 to 250 mW mm^{-2} were used. It should be noted that since the intensity of Raman scattered radiation from a sample is dependent on excitation power and the Raman experiment is generally performed as a single-beam experiment (i.e. no ratio performed to correct for source fluctuations), the laser power must be constant for quantitative studies. The authors also state that the degree of spectral difference for the polymorphs of most compounds is similar when comparing FT Raman and FTIR spectra. The exception is that the IR spectra of polymorphs involving hydrogen bonding tend to show larger differences than those observed in their Raman spectra. Spectra were analyzed using a commercially available modified principle components regression analysis package. Experimental characterization of two of the polymorphs of cortisone acetate by FTRS was reported with standard errors of prediction of less than 2.5% in some cases, showing that in some cases this technique is a reasonable alternative to FTIR for characterizing polymorphs.

Salari and Young[23] used FTIR/ATR to identify and quantify the three polymorphs of a model compound, ganciclovir, in mixtures. They point out that the use of ATR for analyzing polymorphs in pharmaceuticals was suggested by Higuchi et al.[24] in 1969. ATR spectra can be acquired quickly, with little or no sample

preparation required, and this sampling technique is nondestructive. Samples are generally not subjected to excessive pressures, in contrast to the pressures used to prepare KBr pellets to obtain transmission spectra. Experiments were performed to determine the concentrations of the three known polymorphs of the antiviral, ganciclovir. The polymorphs have distinctive spectra in the region between 1800 cm^{-1} and 600 cm^{-1}. The calibration set included the pure polymorphs along with binary and ternary mixtures prepared from the pure polymorphs.

ATR spectra were acquired with the use of a commercially available, 9-bounce diamond horizontal ATR accessory. Limited pressure was applied to maintain contact between the sample and the diamond ATR element. The PLS algorithm was used for quantitation. The mean absolute errors between actual and predicted concentrations of the polymorphs in the mixtures for one of the validation sets ranged from approximately 3 to 6 w% and were polymorph dependent.

Crystals of famotidine, an H_2-receptor antagonist, have been studied by several researchers using several spectroscopic methods, including FTIR.[25,26] The solubility and therefore the bioavailability of the different polymorphs of a drug may be different, which is one of the reasons necessitating the efforts to identify and characterize them. Hagedüs et al.[25] studied two polymorphs of the drug crystallized from water. To prepare one form, the water was allowed to cool very slowly while the second form was prepared by pouring the aqueous solution over ice. FTIR spectra were recorded at 1 cm^{-1} resolution for the crystals dispersed in KBr and pelletized. Spectra for the two polymorphs obtained are clearly different. Using the absorption band at 3506 cm^{-1}, it was estimated that the presence of between 1% and 2% of the crystal form prepared by the rapid cooling method could be determined in a mixture being primarily the crystal form obtained by slowly cooling the aqueous solution.

Hassan et al.[26] prepared and characterized three polymorphic forms of famotidine which were determined to be present in crystals prepared from several solvents and mixtures of solvents. The ''A'' form was crystallized slowly from acetonitrile. The ''B'' form was crystallized from methanol and mixtures of water–methanol, methanol–diethyl ether, acetonitrile–diethyl ether, tetrahydrofuran–diethyl ether, tetrahydrofuran–n-hexane, methanol–benzene and methanol–toluene. The ''C'' form was prepared by dissolving the famotidine in boiling tetrahydrofuran followed by filtering and adding diethyl ether so that the crystals formed in a tetrahydrofuran–diethyl ether solution. Transmission IR spectra were acquired for the crystals prepared as KBr pellets. It was noted that grinding and the pressure required to prepare the KBr pellets did not affect the polymorphic form of the compound. Significant differences were observed in the spectra of the A crystal form, which was prepared from acetonitrile and crystals obtained from tetrahydrofuran–ether or methanol. A distinct peak at 1672 cm^{-1} was observed for the crystal form obtained from acetonitrile. A similar absorption was observed by Hegedüs et al.[25] for one of the polymorphs that they had characterized. Likewise, both groups observed a peak at 3506 cm^{-1} in one of the crystal forms. Other spectra observed for the two other crystal forms were also highlighted.

An idea of the range of applications of MIR spectroscopy can be seen in the following examples. Wasacz et al.[27] described the use of MIR diffuse reflectance data to determine the hydration state of pharmaceuticals, specifically a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor. They described the spectral differences that are observed when spectra are taken for the sample incorporated into a KBr pellet or taken by diffuse reflectance without use of a halide diluent. Diffuse reflectance data were acquired at several temperatures, from 25 to 185 °C for samples which had been exposed to different atmospheric humidity conditions. They monitored the spectral features for adsorbed water and water of hydration which is incorporated into the crystal. Also monitored were changes in the OH stretching region for magnesium sterate, a compound commonly used in pharmaceutical formulations, which exists in anhydrous and several hydrated forms. Differences observed in the OH stretching region for spectra acquired by the variable temperature DRIFT technique allowed the characterization of both the di- and trihydrated forms of this compound. Their conclusion was that using variable temperature DRIFT spectroscopy and exposing the compound to different humidity conditions provided ''unambiguous characterization of the pharmaceutical hydrates''.

Several papers have reported using FTIR spectroscopy to monitor interactions between pharmaceutical compounds and carriers. Hirasawa et al.[28] described using FTIR spectroscopy to characterize interactions between naproxen and lactose, which was used as the carrier for the solid dispersion. Samples were prepared by mixing various proportions of the drug, heating to 220 °C, which is the melting point of lactose, stirring the resulting melt to provide a homogeneous mixture, and then rapidly cooling to solidify. FTIR spectra were acquired for the solid samples as KBr pellets. Monitoring the bands in the carbonyl region for crystalline naproxen, and both physical mixtures and solid dispersions of naproxen and lactose provided information on the type of interactions which occur for the drug in the solid dispersion. The spectra of the carbonyl region for these samples provided information on the presence of the free carboxylic

group, a dimeric structure and a hydrogen bonding interaction between the lactose and naproxen. In the solid dispersions, the degree of hydrogen bonding between the lactose and the drug was found to be dependent on the carrier/drug ratio.

FTIR spectroscopy has also been used to monitor changes in the matrix of polymer-based, controlled-release delivery systems.[29] It has been used as part of a study to characterize degradable poly(lactide-*co*-glycolide) (PLGA) films employed to deliver tetracycline. Of particular interest for this study was the effect of incorporating a soluble salt, sodium chloride, at different loadings into the polymeric system. Drug release studies were performed by placing the tetracycline containing film samples in phosphate-buffered saline and held at 37 °C for up to 42 days. Samples of the films were taken at predetermined times and lyophilized. FTIR spectra of cast films of these samples were acquired up to the 21-day time point. Peaks which are characteristic for lactic acid, glycolic acid, and PLGA observed in the 1400–1500 cm^{-1} region were monitored over time. While no change in the peak intensities was observed during the first day of immersion, for samples removed in subsequent days the intensity of the glycolic acid and PLGA peaks decreased relative to the lactic acid peak. These changes in relative peak intensity with time were interpreted to indicate a difference in the rate of degradation between the glycolic acid components and the lactic acid components of the polymer. Spectral differences were also noted in the 1000–1300 cm^{-1} region for samples with and without sodium chloride incorporated into the polymer. These differences were interpreted to indicate that the salt containing samples were more crystalline.

FTIR, X-ray diffraction (XRD) and thermal analysis were used to characterize formulations of the calcium-channel blocker, nifedipine, in binary systems with the phospholipids, dipalmitoylphosphatidylcholine (DPPC) or dimyristoylphosphatidylcholine (DMPC).[30] It is been shown that the dissolution and absorption of drugs which are very sparingly soluble in water can be improved by formulating with small amounts of a phospholipid, such as DPPC or DMPC. The study included physical mixtures, solid dispersions and ground mixtures of nifedipine and phospholipid at approximately 9 : 1 w/w ratios. FTIR data were acquired for these samples as KBr pellets. The authors concluded, based on the FTIR spectra obtained, that preparing the nifedipine–phospholipid mixtures by either grinding or coprecipitation resulted in no molecular or crystal structure changes.

The ability of specific compounds to enhance the transdermal delivery of drugs has been investigated on humans, in vivo, using ATR coupled with FTIR.[31] Oleic acid is known to be a skin permeation enhancer. Such compounds reduce the skin barrier function, which has been correlated with increased transepidermal water loss (TEWL). Studies were performed exposing the patches of skin on the arms of the volunteers with test solutions of mixtures of oleic acid and propylene glycol. Both TEWL and ATR/FTIR measurements were performed. The FTIR measurements were made by placing a ZnSe ATR element directly in contact with the skin. The area of skin sampled was 7 cm^2.

The IR absorption bands in the carbon–hydrogen stretching region (~3000 cm^{-1}) and the carbonyl region (~1720 cm^{-1}) were monitored to ascertain the location and effect of oleic acid on the skin. The position and bandwidth of the methylene asymmetric stretches of the stratum corneum lipids provided an indication of the perturbing effect that the oleic acid has on the stratum corneum lipid barrier. The greater the perturbation, the larger the shift of the methylene asymmetric stretching frequency to higher wavenumber. Carbonyl bands at 1740 cm^{-1} and 1710 cm^{-1} were used as indicators of the esterified carbonyl group of the esterified lipids and the free carbonyl group of the oleic acid, respectively. Monitoring the absorbance of the free carboxylic acid group provided an indication of the movement of the oleic acid from the surface either by diffusing deeper in the skin or spreading laterally through the skin. Changes in the 1710 cm^{-1}/1740 cm^{-1} absorbance ratio over time could also possibly indicate esterification of the oleic acid functional group.

An interesting application of FTIR/ATR of interest for pharmaceuticals is the determination of diffusion coefficients for liquids in anhydrous lanolin and poly(ethylene glycol) (PEG) ointment.[32] The diffusion coefficients were determined for several test liquids, including pyridine, acetophenone, methyl salicylate, and 4-chloro-4′-fluorobutyrophenone. A horizontal ATR cell with a 45° angle of incidence ZnSe ATR element was used for these measurements. The experiments were performed by placing a layer of lanolin or PEG ointment on the ATR element. The layer was contained in a template prepared by punching a hole in a 0.157 mm-thick sheet of Teflon®. The thickness of the layer was limited to the thickness of the template by scraping off any excess with a razor blade. A bead of the same material was placed around the hole and served as a liquid barrier. The diffusion coefficients were determined by placing 20-μL aliquots of the test solution in the well formed, and acquiring IR spectra over time as the compounds diffused into the layer. The depth of penetration of the IR beam into the layer was estimated to be from 0.6 to 0.9 μm. As the concentration of the liquid within this depth of penetration increased with time due to diffusion, the magnitude of the absorbance of the characteristic peaks for the liquid increased. The increase in absorbance was monitored over time with these data used to calculate the diffusion

coefficients for the test liquids. The diffusion coefficients measured ranged from 0.56×10^{-7} to 7.2×10^{-7} $cm^2\,s^{-1}$.

Many studies have shown that particle size is an important variable that must be controlled to obtain quantitative results from diffuse reflectance FTIR measurements.[33,34] Otsuka and Matsuda[33] exploited the relationship between intensity of light absorbed and particle size, as derived by Duyckaerts,[35] to measure the particle size of phenytoin in pharmaceutical preparations. Diffuse reflectance spectra were obtained for the phenytoin powders dispersed in micronized KBr powder at 0.5%. The reflectance spectra obtained were corrected using the Kubelka–Munk relationship. The intensity of the phenytoin absorption at 1724 cm^{-1} was measured after correcting the baseline in that region. A linear relationship was found between the absorbance at 1724 cm^{-1} and the reciprocal of the mean particle size, both for pure phenytoin and a binary mixture of phenytoin and lactose.

One of the strengths of MIR and NIR spectroscopy is the ability to analyze solid samples directly. Solid dosage forms of benzodiazepines were studied by reflectance spectroscopy by Ficarra et al.[36] These studies were performed using a dispersive IR spectrometer operating at 8.5 cm^{-1} resolution at 2000 cm^{-1}. Samples were mixed with KBr powder in proportions of 1 : 10 w/w. Plots of the Kubulka–Munk transformed reflectance data versus wavenumber were produced for several pure benzodiazepines. Diazepam in both laboratory-prepared excipient mixtures used to simulate the commercial drug product and commercially available capsules were analyzed using the same sample preparation procedures. The results presented indicate that using this method the concentration of diazepam in drug product can be determined with a high degree of confidence.

The use of NIR and MIR diffuse reflectance spectroscopy to verify the identity and content of drug formulations in both capsules and tablets was investigated.[37] The goal of the study was to develop a method for routine identity testing for clinical packaging. Requirements included that the method be rapid and could be applied by minimally skilled technicians. Formulations containing simvastatin, enalapril maleate, lovastatin and finastride were employed in this study. Distinguishing between lovastatin and simvastatin, which differ only by an α methyl group of an ester carbonyl, was taken as a difficult identification problem. The MIR region was found to be capable of providing such discrimination, while NIR spectra were not able to provide as clear discrimination at low concentrations. Sample treatment included milling the capsules and tablets with a grinding mill. A grinding time in excess of 5 min was found to affect the quantitation but not drug identification. A resolution of 8 cm^{-1} was determined to be sufficient for this analysis. For tablets and capsules containing 0.2–40 mg of drug, the method was capable of determining 1% (w/w) of drug in the specific formulations tested.

Proteins of pharmaceutical interest have also been the subject of MIR studies. ATR/FTIR was used to study silk fibrogen gel, which was being investigated as a new oral dosage form for elderly patients.[38] Silk fibrogen is a protein which is harmless to humans, has unique properties, and provides a dosage form with a jelly-like consistency, which makes it easier to swallow. Spectra were acquired for the silk fibrogen in solution and as a gel by ATR using a germanium ATR element. Changes in the structure of the protein from random coil to β-structure as the protein gels were determined by monitoring the amide I and amide II bands of the protein between about 1650 cm^{-1} and 1520 cm^{-1}.

Carpenter et al.[39] reviewed the use of MIR spectroscopy for monitoring the secondary structure of proteins to establish formulations which provide stable lyophilized products. It is known that some excipients can prevent proteins from denaturing during the freeze-drying process. Using IR spectroscopy, the secondary structure of the protein can be monitored in aqueous solution, the frozen sample and as a freeze-dried solid. Comparison of the secondary structure, especially the degree of unfolding of the protein, is indicative of the stability of the freeze-dried product. The positions of the amide I bands of the protein, which occur in the 1700–1600 cm^{-1} region, are sensitive to the secondary structure of the protein. Monitoring changes in the band intensity and position provides information on changes in the native state of the protein in going from the protein in aqueous solution to the lyophilized solid. The effect of excipients, such as sucrose, on the stability of the protein can thus be evaluated. Obtaining the IR spectra for aqueous solutions containing several milligrams per milliliter is reasonably straightforward with the use of appropriate, short-pathlength sample cells and modern FTIR instruments. Spectral data processing, however, can be somewhat involved since the amide I bands of the protein overlap the strong water absorption band in this region. Spectral subtraction is performed to remove the water contribution from the spectrum of the protein in solution. The amide I bands of the protein are broad and overlapping, but taking the second derivative of the resulting spectrum assists in determining the positions of the individual amide I bands of the protein. The positions of these bands are indicative of the presence of the various secondary structures (i.e. α-helix, β-sheet, unordered) present in the protein.

Often FTIR instruments are coupled with other instrumentation resulting in a powerful analytical tool for a specific type of analysis. Rodriguez and Bugay[40] combined a thermogravimetric instrument with an FTIR instrument using a commercially available interface to

determine the identity of the compounds volatilized from a sample upon heating. The evolved gases were carried using helium into a multipass gas cell which was held at 160 °C. FTIR spectra were acquired at a rate of 1 min^{-1} at a spectral resolution of 4 cm^{-1} as the samples were heated from ambient temperature to 300 °C at a rate of 10 °C min^{-1}. The availability of spectral libraries of vapor phase species simplifies compound identification. Experiments can be performed on a little as 1 mg of sample and analysis times are short. Basically, the experiment follows the weight loss of the material as the temperature increases and correlates changes observed in the spectrum of the gas in the spectroscopic cell with changes in the sample's mass.

Studies were conducted to determine the form of several solvates and provide information on the presence of residual solvents for several pharmaceutical compounds. One example presented shows how the authors used the combined thermogravimetric analysis (TGA)/FTIR technique to determine that a butyl acetate solvate was formed in a 1 : 1 mole ratio for a compound under investigation for the treatment of hypercholesterolemia. The authors show that TGA/FTIR, when used in combination with other techniques such as differential scanning calorimetry (DSC) and XRD, provides a powerful tool for studying solid pharmaceuticals.

Photoacoustic (PA) spectroscopy is another hybrid spectroscopic technique which, although not as widely utilized as the other sampling techniques discussed, may provide unique advantages for some pharmaceutically important sample types.[6] The FTIR/PA spectroscopy experiment is based on the principle that when a sample absorbs light, a portion of the energy absorbed is dissipated as heat. If light is absorbed close to the surface of the sample, the temperature of the surface and the atmosphere immediately surrounding the sample will increase. Modulating the source of the light results in a modulation of the surface temperature, and likewise the temperature of the surrounding atmosphere, resulting in the formation of an acoustic wave which can be detected using a microphone. PA spectra have been acquired using both dispersive IR and FTIR instruments. The use of FTIR instruments employing step-scan, rather than continuously scanned, interferometers for PA applications has been of recent interest.[41,42]

Neubert et al.[43] used FTIR/PA spectroscopy to determine the concentration of the drugs dithranol and brivudin in a petroleum jelly formulation. To determine the concentration of active ingredient in such formulations often requires the use of a separation technique such as high-performance liquid chromatography (HPLC) or capillary zone electrophoresis (CZE) to physically separate the active ingredients from the matrix prior to quantitation. Spectroscopic techniques can eliminate the need for employing a physical method of separation, with the minimal sample preparation required for the PA technique being a major advantage. Using bands between 1545 cm^{-1} and 1770 cm^{-1} for brivudin and between 1560 cm^{-1} and 1670 cm^{-1} for dithranol a good correlation was found between the concentrations determined by HPLC and by PA spectroscopy for samples ranging in concentration between 1.0 and 10.0 wt% dithranol in petroleum jelly and for CZE and PA spectroscopy between 0.5 and 10.0 wt% brivudin in petroleum jelly. The integrated intensities for the bands of dithranol and brivudin were ratioed to the intensity of a band due to the petroleum jelly. The data were acquired using a step-scan interferometer with a total scan time of approximately 21 min. The PA spectra were acquired at a resolution of 12 cm^{-1} and were normalized by ratioing to a spectrum of carbon black.

One area which has potential for being utilized more for pharmaceutical applications is vibrational optical activity (VOA). Though VOA includes both Raman optical activity and the corresponding IR version, vibrational circular dichroism (VCD), recent developments are the reason for concentrating on VCD here.[2,44] VCD can be used to obtain information on the optical purity of a mixture of enantiomers, help determine the absolute configuration of a molecule or provide conformational information.

The basis for VCD is that optically active molecules interact differently with right circularly polarized light than left circularly polarized light. One of the enantiomers of a molecule may, for example, absorb more right circularly polarized light, than left circularly polarized light at the same wavelength. A VCD instrument is designed to measure the difference between the amount of light absorbed for the two polarizations at a given wavenumber, or ΔA. The VCD spectrum is a plot of ΔA vs wavenumber.

The magnitude of ΔA is very small, approximately 5×10^{-4} times the magnitude of the absorbance.[2] Measuring such a small difference between the amount of light absorbed for the different polarizations makes the measuring of a VCD spectrum instrumentally challenging. Both dispersive and FTIR-based VCD instruments have been assembled. The modification of either instrument to acquire VCD spectra involves passing alternately left and right polarized light through the sample and measuring the difference in the amount of light absorbed. To produce the left and right circularly polarized light, two polarizers are placed in the optical train prior to the sample. First, unpolarized light produced by the IR source is linearly polarized by passing through a wire grid polarizer. This linearly polarized IR light then is converted to either right or left circularly polarized

light using a photoelastic modulator (PEM). The PEM is operated so as to alternately produce right and left circularly polarized light.

VCD, in addition to providing information on absolute configuration of an optically active compound is also capable of providing information on the conformation of such a compound in different environments. For example, Nafie and Freedman[44] discuss the use of VCD for studying the conformation of the antiarrhythmic drug, (*S*)-propranolol, in solution. The recent introduction of a commercial, dedicated, FTIR-based, VCD instrument has the potential to increase the use and importance of VCD for pharmaceutical applications in the future.[44]

5.2 Near-infrared Spectroscopy

One of the best places to get started for anyone interested in NIR spectroscopy is the many reviews on NIR applications in the pharmaceutical industry.[8,19,45–48] NIR spectroscopy has been employed for the analysis of pharmaceuticals for over 30 years. The history of the application of NIR to pharmaceuticals has been reviewed by Kirsch and Drennen.[46] The review also discusses briefly the many chemometric methods which have been applied to NIR spectra and reviews the application of NIR of solid dosage formulations and intact dosage forms. In order to obtain NIR spectra for solid dosage forms, the authors indicate that sample positioning is one of the most important variables in the experiment, being the ''single largest source of error''. One approach to reducing this error is to acquire several spectra of a given tablet while rotating the tablet between spectral data acquisition. The average spectrum for the tablet is then computed thereby reducing the errors associated with positioning.

Corti et al.[47] indicate that several of the advantages of NIR spectroscopy include being nondestructive, noninvasive and applicable to many sample types. Another advantage is that the lack of response of glass in the NIR region allows samples in glass containers to be analyzed. The authors also comment that the shorter wavelengths in the NIR result in more linear and reproducible calibrations for data acquired using diffuse reflectance as compared to the use of this sampling technique for obtaining MIR spectra. One of the limitations of NIR analysis mentioned is that the calibration standards must be analyzed using an independent reference method. Two of the most important aspects of the NIR analysis are the choice of the chemometric model for quantitation and determining which standards to use for calibration. Corti et al.[47] discuss briefly the differences between the multiple linear regression (MLR) method and the full spectrum methods of principal component analysis (PCA), principal component regression (PCR) and PLS. Pretreatment of the data prior to the application of these models is also a consideration. Choosing the correct number and type of standards is also critical. Clearly the goal is to maximize the information provided by standards that are representative of the samples to be analyzed while minimizing the number of standards and time required to perform the calibration. Approaches to determining the correct standards for calibration are discussed. Several applications of NIR analyses are also discussed.

Another excellent, detailed source of information on NIR analysis of pharmaceuticals is the recent review by Blanco et al.[8] which sites over 200 references. Many examples are provided on both quantitative and qualitative NIR analyses. Sampling and data treatment methods are also discussed. A timely section listing the websites of many Internet sources of NIR information is also provided.

Higgins[48] provides an insightful evaluation of the use of NIR spectroscopy for industrial pharmaceutical applications. Among the points raised are that NIR spectroscopy is very useful for confirming the identity of materials and that the technique is ideal for pharmaceutical applications since the materials are generally organic and of high purity. Clearly this application is based on having high-quality raw material standard reference spectra available. The nondestructive nature of this type of analysis along with its ability to sample through many types of containers, including plastic bags, blister packages, disposable glass vials, and other packaging materials, also adds to the versatility of the technique. Liquids and powders can also be conveniently and routinely sampled. The application of NIR spectroscopy to monitoring raw materials, in-process monitoring, and postproduction monitoring, are highlighted. An example presented is the use of NIR spectroscopy to evaluate the degree of powder blending in production. In this example, the spectral response of both the active ingredient and excipients are indicative of the degree of homogeneity of the product and, thus, an indicator of the extent of blending which has taken place. Other applications mentioned include the use of NIR spectroscopy for the quantitative determination of water in freeze dried injection products, direct assays of bulk tablets and monitoring fermentation processes. One important point raised by the author, concerning the pharmaceutical applications of NIR spectroscopy, is that validated methods using NIR technology are now accepted by pharmaceutical regulators. Higgins also points out that NIR spectroscopy must eventually be accepted as a replacement for other, more traditional, methods of analysis.

Catalano[49] discussed the implementation of NIR in the process environment. Included in the discussion were the different worlds in which the people who are involved in dealing with the process and the laboratory people

exist as well as differences in the environments in which process and laboratory instruments must operate. He also states the importance of working with a vendor in the development of process monitoring applications since the vendor should have more experience in performing such analyses under process conditions. Interestingly, Catalano stresses the importance and roles of the people involved in developing and implementing the NIR application in the process environment, especially for environments where there is no history of using such instrumentation for process applications.

Ciurczak[50] explains the development of NIR spectroscopy from the time of the discovery of this region of the electromagnetic spectrum by Hershel, through the development of the early instruments and applications of NIR to food products. Comparisons are made between MIR spectroscopy and NIR spectroscopy. What is interesting is that those factors which are often thought of as being limitations in MIR spectroscopy are exploited in NIR spectroscopy, especially for process applications. For example, MIR spectroscopy is often thought of as being an insensitive technique by analytical chemists due to the molar absorptivities being several orders of magnitude lower than those found in the UV/VIS region. The molar absorptivities in the NIR region are approximately an order of magnitude lower than those in the MIR region, which leads directly to the use of longer pathlengths for NIR measurements. The need to use longer pathlengths and/or higher concentrations, while generally thought of as a limitation in the analytical laboratory, is a benefit in process analysis. The limited sensitivity in the NIR region allows the use of larger pathlength flow-through sample ''cells'' which do not clog and reduce the need to dilute samples or otherwise handle the samples, as is often required when using other forms of spectroscopy. Ciurczak also briefly describes the need for mathematical data manipulation to obtain quantitative results from the NIR data acquired. Several methods and applications are mentioned. The importance of having samples and standards analyzed by a primary method available for calibration of the NIR system is also stressed.

Determining the moisture content of final drug products and components is often important. NIR spectroscopy provides a means for nondestructive analysis which requires little if any sample preparation. Zhou et al.[51] evaluated the effect of several experimental variables on the determination of the moisture content of hygroscopic drug substance at moisture levels ranging from 0.5 to 11.4% (w/w). These analyses make use of the strong water absorption bands in the NIR region (1420 and 1920 nm). Diffuse reflectance spectra were acquired from 1100 to 2500 nm for the samples in sealed glass bottles, with 16 scans being averaged for each spectrum. The reflectance spectrum for each sample was ratioed to the spectrum of a white ceramic reference. The authors chose to analyze the spectral data obtained using PLS although simple linear regression and MLR are also often employed for such analyses due to the strong water absorptions and lack of spectral interferences in these regions. The ability of PLS to remove spectral noise and model nonlinearity were given as potential reasons for using the method for this application. The results indicate that a standard error of prediction of 0.11% could be obtained in the moisture range studied for these hygroscopic samples in sealed glass containers. The use of first derivative spectra does provide a better calibration model for the 1850–1936 nm region.

Berntsson et al.[52] used NIR diffuse reflectance spectroscopy to determine the water content of hard gelatin capsules with analysis times of approximately 2 min. As in the previous example the spectra containing the strong water absorption bands were acquired in the 1100–2500 nm region. The moisture content of the capsules is important, since if it is above approximately 18% the capsules become soft, whereas below a water content of approximately 10% the capsules become brittle. Thus, the moisture content of the capsules needs to be checked before filling, which is why a fast, at-line method for moisture content evaluation is of interest. These researchers compared the results obtained using diffuse reflectance NIR spectroscopy with data obtained from loss on drying experiments. Calibration standards of the gelatin capsules were prepared by placing the gelatin capsules in chambers having known constant relative humidity for up to 20 days. A low moisture standard was also prepared by placing gelatin capsules in a chamber with desiccant for 5 days.

MLR and PLS were utilized to process the spectral data acquired. The effects of several spectral manipulations performed prior to fitting the data were also evaluated. They found that MLR using three wavelengths chosen by an iterative procedure produced the best calibration model for the data presented. Interestingly, none of the wavelengths chosen were the most intense for water absorption. All 70 wavelengths were used for calibration with PLS, which is a more robust technique than MLR and can detect outliers. The PLS weighting vectors, unlike the selected wavelengths in MLR, were found to be heavily weighted towards the regions where water absorbs strongly. Though reportedly not observed in this study, it was noted that other researchers have observed wavelength-independent changes in the spectral baseline with water absorption on silica.[53] It was also noted that while empty, hard gelatin capsules were used for this study, the method should also be applicable to filled capsules, assuming appropriate calibrations standards are utilized.

Borer et al.[54] evaluated the important sources of variability for analyses using NIR reflectance spectroscopy. The study concentrated on determining dose levels for tableted drug product samples. Several potential contributors to variability in the NIR measurement were evaluated, including the iris or aperture setting, the segment, which is a calculation variable indicating the number of data points over which the slope is calculated when converting the spectral data to a second derivative spectrum, the orientation of the sample platform, the number of scans which are averaged to obtain a spectrum, the number of samples of each tablet analyzed, the time in days over which the experiment is performed and the frequency at which a reference spectrum is acquired. The magnitude of the contribution of each of the sources of variability was evaluated. For example, the authors concluded that the segment value was a significant factor in the variability observed in the study indicating the slope should be calculated over 10 points. The orientation was important for embossed samples, while the number of scans was not an important source of variability. The effects of other potential sources of variability, including lot-to-lot variations in the tablets, inhomogeneity within a lot of tablets, and temperature were not evaluated in this study. The study shows the importance of evaluating the magnitude of the contribution of each of the many potential sources of variability in NIR and other spectroscopic analyses.

Comparisons between different data acquisition methods, types of NIR instruments and data manipulations for quantitative analyses of solid pharmaceutical samples was evaluated by Dreassi et al.[55] Experiments were performed using two NIR instruments, one an FT NIR instrument and the other a dispersive NIR instrument. The methods of sampling compared included direct diffuse reflectance measurements of the samples and sampling using a fiber optic probe. The PLS algorithm was employed for quantitation. Samples analyzed included powders containing benzydamine hydrochloride and tricetol, as well as ibuprofen and paracetamol as pills or tablets. Quantitation based on the second derivative spectra were found to provide the best calibration. The authors comment that using higher derivative spectra reduces the effects of particle size on the reflectance data obtained, thereby improving calibrations for samples having a distribution of particle sizes.

Wargo and Drennen[56] used diffuse reflectance NIR spectroscopy to characterize the degree of homogeneity of powder blends. Blend homogeneity is an important consideration in preparing drug product and is typically measured prior to tableting or encapsulation. The homogeneity of blends of hydrochlorothiazide, fast-flow lactose, croscarmellose sodium and magnesium stearate were investigated in this study. Data were acquired using a dispersive NIR instrument by collecting spectra from 1200 to 2400 nm sampling directly through the bottom of the borosilicate sample vials. The homogeneity of a blend is often determined by measuring the amount of the active ingredient in several samples from the same batch. If the active ingredient is found to be homogeneously distributed, the other components of the blend are also considered to be evenly distributed. Data treatment for the NIR spectra included linearization by performing a $\log(1/R)$ transformation, where R is the reflectance. The homogeneity of samples with the same component concentrations mixed for different time intervals in a twin-shell blender were assessed. The degree of homogeneity for a separate blend sampled over time was also assessed. The reflectance data obtained were evaluated to determine sample homogeneity using three methods: chi-squared analysis, the bootstrap error-adjusted single-sample technique (BEST) and the modified BEST technique. Second derivative spectra were calculated prior to performing a PCA. Chi-squared analysis is performed on individual wavelengths while the two BEST techniques utilize the entire spectrum. The results obtained indicate that NIR spectroscopy has great potential for assessing blend homogeneity as well as being a useful tool in studies designed to determine optimal mixing time and conditions.

The sampling and sample handling techniques used for acquiring spectral data is only one of the issues that must be addressed when determining an appropriate method for an analysis. The approach taken to process the spectral data is often a major concern in developing the analytical method. Often an analytical method is developed to confirm the classification of samples in a given group. One example of this type of analysis is the verification of drug lots used for clinical studies. Candolfi et al.[57] evaluated several approaches to processing the NIR reflectance data obtained for capsules and tablets containing several concentrations of active ingredient, several excipients and for several lots. The goal was to determine which data-processing method was best for classifying the spectral data obtained. Discriminating methods were the focus of the study. A comparison was made using both parametric methods (linear discriminate analysis and quadratic discriminate analysis) and nonparametric methods (K-nearest neighbor). NIR reflectance data were acquired for the spectral region from 10 000 to 4000 cm^{-1} for the powdered tablets and capsules using a FT/NIR instrument. The authors conclude that for clinical study lots it might be best to use a two-step approach for final classification. The first step is to discriminate between the different classes present and the second step is to use another data treatment method to positively identify the sample.

Blanco et al.[58] studied the effect which the choice of calibration standards has on the quantitative results obtained for NIR diffuse reflectance analysis of both the active ingredient and major excipients of a solid pharmaceutical formulation. An optical fiber probe was used to acquire the spectroscopic data. The active ingredient for this study was otilonium bromide with microcrystalline cellulose, maize starch and sodium starch glycolate excipients. The importance of using standards for calibration which adequately represent the variability expected to be observed in the samples was discussed. Sources of variability between laboratory-prepared standards and standards obtained from production runs were discussed. The need for the use of a multivariate calibration method, such as PLS regression analysis, is demonstrated. The quantitative results obtained using both laboratory-prepared mixtures of the ingredients with and without additional production samples as standards are presented and discussed. The effects of calibration standards choice, spectral region used for analysis and several mathematical treatments of the spectral data, including first and second derivative spectra, were evaluated. This study clearly points out the importance of systematically evaluating how representative the standards used for quantitation are when developing a NIR diffuse reflectance method and throughout the life of the application of the method developed.

Sources of variability in the NIR data were investigated systematically for tablets, and hard and soft gelatin capsules by Candolfi et al.[59] Changes in both chemical and physical variables are possible sources of the spectral variability observed in such analyses. The tablets and capsules sampled contained both active ingredients, ranging from 4 to 10% in concentration, and between 4 and 10 excipients. The active ingredients were different for the various sample types. The major excipient for the tablets was lactose while the major excipient for the hard gel capsules was cellulose. The sources of error evaluated included positioning of the sample, batch-to-batch variability, interday variability and within-batch variability. The effects of spectral preprocessing methods, such as second derivatization and standard normal variate transformation on the results obtained was also evaluated. It was pointed out that while data processing and manipulation can overcome some of the variability observed in the spectral data obtained, improving the quality of the data is also important. One variable which must be controlled is the moisture content of the samples. Water absorbs strongly in the NIR region. Even if the regions of the strongest water absorption bands are avoided in interpreting the spectral data, water also affects the baseline throughout this region. Instrumental drift was also noted as problematic. These authors suggest that to improve the quality of data obtained, the NIR instrument should be located in an area where both the temperature and humidity are controlled.

The major sources of error were found by Candolfi et al. to differ for the different sample types evaluated. For example, sample positioning was found to be an important variable for both the soft and hard gelatin capsules examined. Time was also found to be a significant cause of the variation observed for these samples. One problem with analyzing gelatin capsules which could add to the variability observed is that the gelatin is sensitive to changes in humidity. For tablets, significant batch-to-batch and within-batch variability was observed which indicates a large number of representative samples which must be included in the training sets for this type of drug delivery system.

An interesting application of NIR spectroscopy assesses the degree of cross-linking of the gelatin-comprising hard gelatin capsules, soft gelatin capsules, and gelatin coatings, which is important due to their wide use in the pharmaceutical, food supplement and cosmetic industries. The degree of cross-linking affects the dissolution properties of these materials. Gold et al.[60,61] have used NIR to study the effect of formaldehyde on both hard and soft gelatin capsules. In one of these studies,[60] NIR spectroscopy was coupled with PCA to monitor the extent of formaldehyde-induced cross-linking in soft elastic gelatin capsules. Capsules were filled with PEG solutions (PEG 400) containing up to 0.40% formaldehyde by volume and allowed to interact for 48 h. The filling solution was then removed and the inside surfaces were thoroughly rinsed with PEG and diethyl ether. Reflectance NIR spectra were obtained for these capsules. Following a series of spectral corrections and mathematical manipulations, the resulting spectra were analyzed using PCA. Baseline shifts were observed which were attributed to changes in the water content of the capsules exposed to the formaldehyde-containing solutions since water is such a strong absorber in the NIR. Changes were, however, also observed in the absorbances at 1780 and 2200 nm which were considered to be the result of changes in gelatin cross-linking caused by the formaldehyde. These spectral changes are likely due to the effects in the NIR region of the spectrum of bonds being formed and broken during the crosslinking process.

Gold et al.[61] also used NIR reflectance spectroscopy to study the effects of exposing empty, unopened, hard gelatin capsules to an atmosphere containing 150 ppb of formaldehyde for up to 24 h. After formaldehyde exposure, the capsules were filled with amoxicillin and NIR reflectance spectra obtained. The NIR data were correlated with data obtained for the dissolution of amoxicillin from the formaldehyde-treated capsules.

5.3 Fourier Transform Raman Spectroscopy

FTRS has many properties which make it attractive for pharmaceutical applications.[62] One important property which has been exploited for biological samples is that water is a weak Raman scatterer, which means that Raman spectra can be obtained for aqueous solutions and samples which contain a high water content. Another of the complications of IR spectroscopy, the requirement that IR-transmitting materials be used for sample containers, is also diminished. Raman spectra can be acquired for samples in glass containers directly, although some care must be taken since the ingredients and impurities found in some glasses may fluoresce when exposed to the intense NIR radiation of the laser source. Probably the most important advantage which FT Raman using NIR excitation has over conventional Raman spectroscopy using UV or VIS wavelengths for excitation is that fluorescence from the sample is generally reduced. Sample fluorescence, which is generally far more intense than the Raman scattering, can result from either a fluorescent analyte or impurities in the sample. The energy of the NIR photons used for excitation in FTRS is not sufficient to result in the electronic transition required for the fluorescence of most species. One other aspect of Raman spectroscopy which is often mentioned is its complementary nature with respect to IR spectroscopy. Absorption bands which are weak in the IR spectrum of the analyte are often strong in the Raman spectrum of the material. One disadvantage of FTRS using NIR excitation, as pointed out by Spragg,[62] is that the high-power, invisible NIR light used for sample illumination gives rise to important safety issues. For this reason, the laser, sample, optics and detector are enclosed in commercial instruments and interlocked to prevent exposure to laboratory personnel.

Petty et al.[63] reviewed the advantages of using Raman spectroscopy, FTRS in particular, for pharmaceutical applications. Many advantages of using FTRS for analysis are noted and several examples are presented. Citing the fact that many packaging materials, again glass in particular, are poor Raman scatterers, which allows spectra to be acquired without removing the sample from its container, Spragg[62] points out that most materials are weak absorbers of the NIR wavelength normally used for excitation in FT Raman. Obtaining Raman spectra for samples in their containers is a rather extreme demonstration that the technique requires little to no sample preparation. An example of an analysis where this property is important is a study involving the compound tegafur, which is cytotoxic.[63] Special handling procedures are normally required when analyzing this material, but can be avoided since Raman spectra can be acquired without removing the sample from its container.[63]

Another important advantage of Raman spectroscopy highlighted by Petty et al.[63] is that it provides an easy means to obtain information on the low-energy vibrations occurring between 400 and 50 cm^{-1}. Most FTIR instruments have a lower wavenumber limit of 400 cm^{-1}, a constraint imposed by the use of KBr optical components (i.e. windows, interferometer, beamsplitter, etc.). To obtain IR spectra in the region below 400 cm^{-1}, the far IR region of the spectrum, requires the use of optical components fabricated from other materials, for example CsI, which is very hygroscopic. Another complication is that water vapor absorbs strongly in the FIR region. Lattice vibrations, which may help distinguish between different polymorphs of a compound, are an example of such low-energy transitions. An example is presented for two crystal forms of an angiotensin II receptor antagonist. Distinct and characteristic differences are observed in the FT Raman spectra in the region between 50 and 425 cm^{-1} for the two crystal forms of the compound.

Hendra[64] explained why FTRS is very often applicable to mixtures of pharmaceutical importance. Raman scattering for noncrystalline, saturated compounds composed of first-row elements is often weak compared with drugs, which are often crystalline, aromatic compounds containing elements not in the first row. Thus, although the drug may be present at lower concentrations than some of the other materials of the drug product, for example a polymer such as cellulose, the Raman scattering as a result of the drug substance may dominate the spectrum obtained. Hendra[64] uses the example of lactose as an excipient which may, however, cause problems since it is a crystalline material and is a strong Raman scatterer. Further, if the lactose in the formulation absorbs water and becomes hydrated, the Raman spectrum of the material will vary depending on the degree of hydration. Hendra[64] also points out that as with IR spectra, the Raman spectra obtained are dependent on the temperature of the sample. It is pointed out that both the intensity and widths of the Raman bands can change with sample temperature.

An early application of FTRS was in the study of drugs which had been dispersed in polymeric materials used in drug delivery systems.[65,66] FTRS using a NIR laser for excitation is more applicable to these analyses than conventional Raman spectroscopy using VIS lasers due to the decreased interference from fluorescence when using NIR excitation and the decreased concern about photodegradation. Poly(sebacic anhydride) is given as an example of a biomedical polymer. The authors point out that by studying changes in the spectral properties of these polymers as the material is exposed to a degradation process provides for the identification of

the end products and the degree of polymer modification. For example, the end products of hydrolysis or exposure to light can be determined simply, often in situ, via FTRS. Such studies may provide information concerning the release of a drug incorporated in the polymer matrix. Analysis of FT Raman spectra of pure drug substance and drug substances dispersed in a polymer matrix provides information on the extent and type of drug – polymer interaction. For example, comparison of the spectra of the drug diclofenac, pure and as dispersed at a concentration of 20% (w/w) in sodium alginate, indicate that there is no molecular interaction between the drug and the polymer. Analysis of concentrations up to 60% (w/w) diclofenac in sodium alginate did, however, show a nonlinear, concentration-dependent intensity change for bands because of the aromatic structure of the molecule. The authors point out that using NIR excitation for FTRS may not eliminate all sample fluorescence and may present some problems for aqueous samples. In another study, Tudor et al.[66] highlighted the use of FTRS using NIR excitation at 1064 nm provided by a Nd : YAG laser and showed spectra for several sympathomimetic amines and poly(anhydrides).

Langkilde et al.[67] employed FTRS to characterize two polymorphs of an unnamed pharmaceutical compound. These two polymorphs are known to be stable at different temperatures and have distinct Raman spectra in the carbonyl region (bands at 1716 or 1724 cm^{-1}) due to the presence of a conjugated ester group which packs differently in the crystal structure of the two forms of the compound. According to these authors the bands are better resolved for the polymorphic forms in the FT Raman spectra than in FTIR spectra, although this may be due to sample treatment. The authors also point out that other researchers have found that polymorphs having distinct IR spectra do not have distinct Raman spectra.[22] A spinning-ring-type sample device was developed and used to increase the area of material sampled; thus the spectra obtained represent more closely a true average for the material present in an inhomogeneous sample. Data treatment included subtracting spectra of each of the pure polymorphs from the spectra of the mixture to determine the contribution of the other polymorph to the observed Raman intensity. For this study, it was determined that the presence of one polymorphic form in the other could be determined from about 1.8 to 15.4% of the minor form. The authors caution that one potential problem is that the absolute intensity of the Raman signal is dependent on particle size, with larger particles resulting in greater Raman intensities. Thus, particle size needs to be considered when performing such analyses, and efforts should be made to control particle size between samples and to ensure that different components in the mixture have the same particle size.

Taylor and Zografi[68] demonstrated the use of FTRS for monitoring the crystallinity of indomethacin powders. The Raman spectra of the γ crystalline and amorphous indomethacin differ in the carbonyl region. Raman-scattering bands for the crystalline and amorphous forms of the compound occur at 1698 and 1680 cm^{-1}, respectively, although there is some overlap due to broadening of the band for the amorphous state. To overcome errors caused by the overlap, spectra were acquired for known standards containing known ratios of the crystalline and amorphous indomethacin. Peak intensity ratios were calculated and used for calibration. Raman spectra were acquired at 4 cm^{-1} resolution using the 1064-nm line of a Nd : YAG laser for excitation. Several different experiments were performed to investigate potential sources of error. The use of intensity ratios overcomes much of the potential error associated with fluctuations in the excitation laser intensity. Although the absolute intensity of Raman scattering increases with increasing laser power, the intensity ratios measured were not found to be very sensitive to such fluctuations. One of the largest sources of error was found to be the homogeneity of mixing of the amorphous and crystalline components of the sample. The effect of particle size on Raman signal intensity also needs to be investigated. The authors, however, indicate that for indomethacin under the conditions studied, FT Raman spectroscopic analysis is capable of detecting the presence of crystalline or amorphous indomethacin to as low as the 1% level with linear calibration being obtained over the entire crystallinity range.

6 CONCLUSION

The range of applications presented show clearly that vibrational spectroscopy, especially MIR, NIR and FTRS, are well suited to analyzing samples of importance to the pharmaceutical industry. The many sampling methods available, the limited sample preparation generally required, and the nondestructive nature of the vibrational spectroscopy, are well suited to the analysis of pharmaceutical products, raw materials, and samples. Discussions with representatives of several instrument manufacturers, however, have indicated that many pharmaceutical applications of their technology, especially in the area of process control and analysis, are proprietary and not reported in the peer review literature. Thus, for some types of applications, important information should be obtained directly from the instrument designers, manufacturers, and suppliers. Instrument manufacturers' Internet websites often prove to be excellent sources of the latest details of instrument design, at least

for that particular manufacturer, and also often provide limited information on proprietary uses for that instrumentation. As with other types of analytical instrumentation, vibrational spectroscopic instrumentation is constantly being developed and improved. Some of the most exciting developments in vibrational spectroscopy are the advances currently being made in vibrational imaging. As the cost of MIR imaging instruments reaches a point where they become more widely available, their use in the analysis of pharmaceutically important samples will be more readily apparent. Likewise, continued developments in FT Raman instrumentation and increases in general availability in industrial laboratories will ensure that the unique capabilities of this technique will be used for pharmaceutically related applications.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Sue Avery, Grace Blinn, and Robert Kowalski of the Genetics Institute Information Center for their assistance in obtaining literature sources. Lisa Housiantis, Stephan Koza, and Hubert Scoble, Biopharmaceutical Characterization and Analysis Department, Genetics Institute, are acknowledged for helpful discussions, suggestions and encouragement throughout. The authors also acknowledge the assistance of Joseph Danahy of Computer Information Services at the University of New Hampshire. Also gratefully acknowledged is the assistance provided by the many experts and representatives of vibrational spectroscopic instrument manufacturers who were contacted. Their willingness to provide information, references, etc., is greatly appreciated.

ABBREVIATIONS AND ACRONYMS

ATR	Attenuated Total Reflectance
BEST	Bootstrap Error-adjusted Single-sample Technique
CZE	Capillary Zone Electrophoresis
DMPC	Dimyristoylphosphatidylcholine
DPPC	Dipalmitoylphosphatidylcholine
DRIFT	Diffuse Reflectance Infrared Fourier Transform
DSC	Differential Scanning Calorimetry
FIR	Far Infrared
FT	Fourier Transform
FTIR	Fourier Transform Infrared
FTRS	Fourier Transform Raman Spectroscopy
HMG-CoA	3-Hydroxy-3-methylglutaryl Coenzyme A
HPLC	High-performance Liquid Chromatography
IR	Infrared
MCT	Mercury Cadmium Telluride
MIR	Mid-infrared
MLR	Multiple Linear Regression
Nd : YAG	Neodymium : Yttrium Aluminum Garnet
NIR	Near-infrared
NMR	Nuclear Magnetic Resonance
PA	Photoacoustic
PCA	Principal Component Analysis
PCR	Principal Component Regression
PEG	Poly(ethylene glycol)
PEM	Photoelastic Modulator
PLGA	Poly(lactide-*co*-glycolide)
PLS	Partial Least Squares
TEWL	Transepidermal Water Loss
TGA	Thermogravimetric Analysis
UV	Ultraviolet
VCD	Vibrational Circular Dichroism
VIS	Visible
VOA	Vibrational Optical Activity
XRD	X-ray Diffraction

The vitamins are a diverse group of compounds, both chemically and analytically, because they comprise a range of biomolecules whose common properties reside solely in the fact that they are essential dietary components, which are needed in relatively small amounts to sustain life and good health. In addition, the major analytical challenges that they present are derived from the facts that (1) there is a need to quantitate them in a wide range of biological matrices, which include both foods and body fluids (for status indices); (2) the concentrations that are present are usually very low, and the ratio to other components, which can be chemically very similar, is small; (3) they may be present in several or many chemically diverse, but biologically interconvertible, forms; (4) some of them are labile to heat, extremes of pH, degradative enzymes and so on and (5) there is no single analytical approach that can quantitate all of them together, within a biological matrix.

They have been divided, broadly, into fat- and water-soluble groups, and each of these has been further subdivided, mainly on a functional basis. Historically, the B-group vitamins were measured by various microbiological assays, and the others were measured (if at all) by semispecific colorimetric assays. Nowadays, there are several more-powerful techniques available, which include high-pressure liquid chromatography, with a range of detectors operating over a continuous range of selective modalities; radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA)-based techniques, which use specific protein-binding selectivities; enzyme reactivation techniques for certain B-vitamin status assays, and so on. The use of mass spectrometry (MS) is gaining

ground and can be combined with several other separation techniques, such as gas–liquid chromatography (GLC), capillary electrophoresis (CE) and so on. Measurement of vitamins in simple pharmaceutical mixtures (vitamin supplements etc.) is now reasonably straightforward.

The technical advances that these methodologies represent have greatly broadened the horizons of the vitamin analyst, and have permitted even some of the more difficult biological matrices to be addressed. However, the unsolved challenges of accurate vitamin analysis show little sign of receding, and there are very few, if any, laboratories worldwide that are currently able to measure all of the known vitamins in all known biological matrices. This remains a major challenge and a goal for the twenty-first century.

1 INTRODUCTION

This article describes the analytical procedures available and problems likely to be encountered for the four fat-soluble vitamins and the nine water-soluble vitamins that are that are generally recognized as being essential organic components in the human diet (Table 1). There are also other dietary organic substances which may be beneficial, or even essential under certain circumstances, but which are not currently recognized or classified as vitamins: these include several carotenoid pigments, a range of bioflavonoid polyphenols, choline, inositol, amino acids such as taurine and so on. These and other organic substances may also be essential vitamins for animals other than man, but this aspect of the subject is not included in the following account. Nevertheless, powerful separation techniques have been developed that can detect and quantitate a large number of organic components in a single analytical run. This is especially true for the carotenoids, which are frequently combined with fat-soluble vitamin A and E analyses.

Each of the vitamins comprises a small group of compounds with interrelated or interconvertible structures and biological functions. Thus chemically related compounds may perform similar functions; each vitamin is converted to several different functional forms within many living tissues and certain degradation products of these vitamins may provide useful evidence about vitamin status even though they are no longer functional. This implies that the analytical methods that are used to measure vitamin contents or status must either measure and summate all of the forms that are present, or measure a representative single form or sample of the forms that are present and then extrapolate to the sum-total of all the forms. Provided that the different forms have similar activities and that they occur in a constant ratio to each other, this is an acceptable compromise, but if this is not the case, then the problem of accurate estimation becomes more complicated. Thus the newer techniques of chemical separation and quantitation may have some disadvantages compared with the older procedures based on bioassay, but since the latter are generally difficult to automate, are usually very time-consuming and lack precision, they are, with some exceptions, steadily losing ground. Table 1 shows the synthetic form for all 13 vitamins, which would normally be used in pharmaceuticals (vitamin supplements, fortified foods etc.), and a small selection of the naturally occurring forms found in foods, blood and tissues. The latter, however, are too numerous to list exhaustively in the present review: for the folates alone, for example, the possible variations in polyglutamate chain lengths, in carbon substituents and in redox state imply several dozen biological variants. In Table 1 an indication of the relative stability of the different vitamins is included. This, too, is a complex subject because each of the different forms of the vitamins has a different stability and because the biological stability may be affected by the matrix, e.g. by protein-binding. However, it is important when planning sample collection and pretreatment procedures for subsequent analysis, to take appropriate precautions against degradation. For most of the vitamins, simple freezing at low temperature is generally adequate, but vitamin C is particularly prone to rapid oxidation, requiring extraction into a metal-chelating acid, such as metaphosphoric acid. The biological forms of folate are also prone to oxidation and will benefit from the addition of a reducing agent.

Vitamins are, by definition, micronutrients, i.e. nutrients that are present and are required in very small amounts compared with the major macronutrient components of the diet, namely the proteins, fats, polysaccharides and sugars. Indeed, nearly all of the vitamins have catalytic functions in living tissues, being recycled and reused in the biochemical pathways in which they participate, whereas the macrodietary components are continuously used up and are not recycled. This implies that the analytical challenge for the vitamins is that of a series of chemically diverse minor components within a complex matrix of major components (in foods, tissues or body fluids) and that the analytical procedures must therefore be capable of extracting them efficiently and quantitating them in the presence of large amounts of potentially interfering substances. The analytical procedures must possess an adequate combination of separation efficiency (without major losses) and analytical specificity to ensure accuracy of estimation and freedom from positive or negative interferences. In the older analytical procedures the extraction step was usually relatively crude and simple and specificity was achieved mainly by biological selectivity, e.g. by microbiological or

Table 1 Natural and synthetic forms of the vitamins and their relative stabilities in aqueous solution

Vitamin	Synthetic form	Some naturally occurring forms	Relative stability in aqueous solutions[a]	Formula
Fat-soluble vitamins				
A	Retinol acetate	Retinol Retinyl esters Retinaldehyde (Retinal) Retinoic Acid	Reasonably stable in non-haemolyzed plasma; less stable once extracted. Store plasma below –40 °C	 *Retinol (Vitamin A)* **(1)**
E	α-Tocopherol acetate	α-, β-, γ- and δ-tocopherols and tocotrienols	Less stable than vitamin A, being fairly easily oxidized. Store below –70 °C	 α-*Tocopherol (vitamin E)* **(2)**
D	Vitamin D_3 (cholecalciferol)	Vitamins D_2 and D_3 and hydroxylated forms, especially 25(OH)– and $1,25(OH)_2$– vitamin D	Reasonably stable in plasma; store below –20 °C	 *Vitamin D_3* **(3)**
K	Menadione	Vitamin K_1 (phylloquinone) and bacterial menaquinones	Reasonably stable in plasma; store below –20 °C	 *Phylloquinone (vitamin K_1)* **(4)**

(*continued overleaf*)

Table 1 (*continued*)

Vitamin	Synthetic form	Some naturally occurring forms	Relative stability in aqueous solutions[a]	Formula
Water-soluble vitamins				
C	L-ascorbic acid	L-ascorbic and dehydroascorbic acids	Extremely unstable in neutral or alkaline solution in oxygen; must be acidified, e.g. with metaphosphoric acid. Store below –70 °C	 *Vitamin C (L-Ascorbic acid)* **(5)**
B_1 (thiamin)	Thiamin hydrochloride	Mainly thiamine diphosphate (cocarboxylase)	Destroyed by heating in alkaline solution. Store samples below –20 °C	 *Thiamin* **(6)**
B_2 (riboflavin)	Riboflavin	Riboflavin phosphate (FMN) and FAD	Destroyed by exposure to light; otherwise stable. Store below –20 °C	 *Riboflavin* **(7)**
B_6 (pyridoxine)	Pyridoxine hydrochloride	Pyridoxal 5¢-phosphate, pyridoxal, pyridoxamine 5¢-phosphate	Very easily destroyed by light exposure. Store below –70 °C	 *Pyridoxine* **(8)**
Folate	Pteroyl glutamic acid	5-methyl and 5-formyl tetrahydrofolates (polyglutamate forms inside cells)	Easily destroyed by oxidation (natural forms only). Store below –70 °C; red cell extracts require a reducing agent, e.g. ascorbic acid as a preservative	 *Pteroyl glutamic acid* **(9)**

B_{12}	Cyanocobalamin	Hydroxo and methyl cobalamins	Fairly stable, but can be destroyed in the presence of ascorbate. Store below −70 °C
Niacin	Nicotinamide, nicotinic acid	Pyridine nucleotide coenzymes: NAD, NADP	Niacin in food is generally stable; the nucleotide cofactors are much less so.
Biotin	*D*-Biotin	Biotin, biocytin, biotin-containing enzymes	Relatively stable
Pantothenic acid	Pantothenic acid	CoA	Pantothenic acid is very stable; CoA is not.

Cyanocobalamin **(10)**

Nicotinamide **(11)**

D-Biotin **(12)**

Pantothenic acid **(13)**

[a] Refers to the naturally occurring forms. For several of the vitamins in tissues the partial degradation of the native forms which occurs during storage of food may not affect the biopotency, even though the analytical patterns change. However, the biopotency of some vitamins is easily destroyed by prolonged storage or cooking (e.g. vitamin C) or light exposure (e.g. riboflavin, vitamin B_6). CoA, Coenzyme A; FAD, Flavin adenine dinucleotide; FMN, Flavin mononucleotide; NAD, Nicotinamide adenine dinucleotide; NADP, Nicotinamide adenine dinucleotide phosphate.

Table 2 Orders of magnitude of concentration of the vitamins and some other major components in adult human blood serum and in two vitamin-rich food sources

Vitamin or other component	Molecular weight[a]	Concentration in human serum ($g\,L^{-1}$)	Concentration in food	
			Soft fruit ($g\,kg^{-1}$)	Liver ($g\,kg^{-1}$)
Protein	–	60–80	10	200
Fat	–	1–10	1	70–100
Glucose	180	1	50[b]	0[b]
Cholesterol	387	1–3	–	2–4
Fat-soluble vitamins				
A	286	$0.3–0.8 \times 10^{-3}$	(0.1×10^{-3})[c]	$100–300 \times 10^{-3}$
E	431	$5–20 \times 10^{-3}$	$0–10 \times 10^{-3}$	$2–4 \times 10^{-3}$
D	385	$(10–50 \times 10^{-6})$[d]	–	$2–10 \times 10^{-6}$
K	451	$0.1–1 \times 10^{-6}$	$20–100 \times 10^{-6}$	$(100–200 \times 10^{-6})$[e]
Water-soluble vitamins				
C	176	$2–20 \times 10^{-3}$	$50–1000 \times 10^{-3}$	$100–200 \times 10^{-3}$
B_1 (thiamin)	301	$1–5 \times 10^{-6}$	$0.1–0.5 \times 10^{-3}$	$2–4 \times 10^{-3}$
B_2 (riboflavin)	376	$50–250 \times 10^{-6}$	$0.1–0.5 \times 10^{-3}$	$30–40 \times 10^{-3}$
B_6 (pyridoxine)	247	$5–30 \times 10^{-6}$	$0.1–1 \times 10^{-3}$	$4–7 \times 10^{-3}$
Folate	459	$3–20 \times 10^{-6}$	$0–300 \times 10^{-6}$	$1–6 \times 10^{-3}$
B_{12} (cobalamin)	1355	$0.2–1 \times 10^{-6}$	–	$0.2–1 \times 10^{-3}$
Niacin	122	–	$1–6 \times 10^{-3}$	$100–150 \times 10^{-3}$
Biotin	244	$0.3–1 \times 10^{-6}$	$2–20 \times 10^{-6}$	$0.3–2 \times 10^{-3}$
Pantothenic acid	219	$1–2 \times 10^{-6}$	$1–4 \times 10^{-3}$	$60–90 \times 10^{-3}$

[a] The molecular weight varies to some extent with the form that is present; the value given is that of the most common form of the native vitamin. For vitamin B_6, this is pyridoxal 5′-phosphate and for folate, 5-methyl tetrahydrofolate monoglutamate.
[b] Total sugars.
[c] As precursor carotenoids; no preformed vitamin A.
[d] Mainly as 25-hydroxyvitamin D.
[e] Mainly as menaquinones.

animal growth assays, using growth media or feeds lacking only the vitamin being tested. More modern procedures generally include more complex extraction steps and/or cleanup and separation procedures to achieve specificity, so that the final quantification procedure can then be less specific but, as a result, is more controllable and precise. Table 2 gives an order-of-magnitude estimate of the vitamin concentrations in human blood plasma and in two types of food, and it indicates the considerable magnitude of difference in concentration between the vitamins and the major components of these typical matrices. The lower the concentration of the vitamins, the greater the analytical challenge; thus vitamins D, K and B_{12} present an even greater challenge than the other vitamins. However, this is only part of the analytical problem, because a multiplicity of different forms (folate), poor stability (vitamin C) or a tight binding to macromolecules (several B-vitamins), all increase the analytical difficulties in addition to their low concentrations.

In the ensuing review it has not been possible to describe all of the variants of all of the analytical procedures for vitamins which have been published: this would be neither feasible within the space available, nor particularly useful, as the reader who requires such detailed information on such a wide range of alternative approaches will need to consult a range of reviews, electronic searches and/or information sources. Therefore I have focused primarily on the principles of the currently used analytical methods with some recent examples. I have also included some examples of newly developed techniques that may become better established in the future, such as CE. Analysis of pharmaceutical preparations is generally more straightforward from the viewpoint of analytical complexity than that of biological matrices; therefore this aspect has received less emphasis than the analysis of blood and urine samples (for status measurements) and of food samples (for food-monitoring and dietary analysis). Some of the older assay methods remain appropriate for laboratories in developing countries, which lack sophisticated modern analytical equipment and the means to maintain, repair and provide consumables for it. Also, dried blood spot methods are being developed for blood collection at sites where no special storage facilities are available, e.g. in developing countries.

Several volumes of the multivolume series *Methods in Enzymology* include a series of specific chapters on selected vitamin analysis methods, with emphasis on practical details and Ball[(1)] has extensively summarized and reviewed the methods that are available for the

analysis of vitamins in foods. There are a number of other useful reviews.[2–16]

All vitamin assays require careful validation and quality control (QC). There are external quality assurance schemes (EQAS) now available for some of the vitamins, mostly for blood (status) assays, and there are also a limited number of biological materials available with assigned values for vitamins to assist with method validation. However, all analytical laboratories will also need to maintain quality assurance (QA) procedures to ensure the long-term stability of their methodologies. This is usually achieved by storing pools of relevant biological sample materials, if possible with three or four different concentrations of each analyte, covering the entire analytical range usually encountered, subdivided into small identical aliquots and stored at very low temperature to ensure long-term stability. By including these QA samples at frequent intervals throughout the course of an assay series, it is possible to assess the extent of drift and of instability in the assay procedures, including the extraction stages (which may be at least as critical as the final analytical run, since the latter is usually calibrated by pure standards). Another important precaution is to add, at as early a stage as possible, a known amount of an internal standard or standards that are similar to the endogenous vitamin(s) but are entirely absent from the sample being analyzed, and which can be quantitated in the same analytical run as the required vitamin(s). These internal standards can then be used to correct for losses during purification, provided these are not excessive. Measurement of the percentage recovery of pure added vitamin gives a further indication of the overall efficiency of the extraction procedures and controls for the presence of interfering effects of matrix components in the assay. An even more powerful technique is to add an isotope (radioactive or stable) of the same vitamin(s) that are being measured and to use the resulting isotope-recovery information to correct for extraction- and purification-related losses. With the increasing availability of MS as an analytical tool, the use of stable isotope-labelled material as an internal recovery standard is becoming increasingly attractive. The formation of characteristic fragments by the breakdown of organic molecules during electron or chemical ionization bombardment in the mass spectrometer, promises to simplify the analytical procedure still further, by reducing the need for complete physical isolation of each organic species.

One important aspect of the analytical program which can only be touched upon in the present article is the principle by which the most appropriate sampling procedures are defined and developed. For foods, some important considerations are the choice of a representative subsample or the sampling of different portions of the entire sample so as to allow for sample heterogeneity. For status assays a choice must often be made between whole blood, serum, plasma, washed red cells or some other cellular component of blood, or a urine sample, which may (or may not) be a timed sample, e.g. 24 h. The blood sample may (or may not) be a fasting sample. Serum, plasma or urine concentrations tend to reflect recent vitamin intakes; blood cellular concentrations usually reflect longer-term intakes and long-term status. For some vitamins, secondary or functional indices such as enzyme activities, or the extent of reactivation of partially cofactor-depleted enzymes by their specific cofactors, may be used to measure and define status, and there is a range of functional status assays that cannot be included in this article (but for which see Bates).[16] Another important question, and a possible pitfall for the unwary, is the variety and choice of different units for reporting concentration. In the case of blood concentrations most journals now insist on SI (Système International d'Unités) (molar) units, but the older literature may also include values expressed as weight/volume, or a variety of non-standard units such as international units (IUs), which require separate definition for each vitamin. The interconversion factors for some of these are given in Table 3. In the case of food analysis the vitamins are generally expressed by weight per 100 g or weight per kilogram of fresh or cooked food. For food analysis it is also essential to define whether the food is cooked or raw, and whether or not it includes the inedible parts, such as the stones of fruit or the bones of meat and fish and so on. It may also be necessary to specify whether the concentrations are expressed on a wet or a dry weight basis. These and

Table 3 Conversion factors for IUs of fat-soluble vitamins[a]

Vitamin	Form	IUs per microgram (IU μg^{-1})
A	Retinol	3.33
	Retinyl acetate	2.91
	Retinyl palmitate	1.82
	β-Carotene	0.56
E[b]	D L-α-Tocopherol acetate (RRR)	1000
	D-α-Tocopherol acetate (RRR)	1360
	D-α-Tocopherol (RRR)	1490
	D-β-Tocopherol (RRR)	750
	D-γ-Tocopherol (RRR)	150
	D-δ-Tocopherol (RRR)	50
	D-α-Tocotrienol	450
	D-β-Tocotrienol	80
D[c]	Cholecalciferol (vitamin D_3)	40
	Ergocalciferol (vitamin D_2)	40
	25-Hydroxyvitamin D	ca. 200

[a] See Hall[1] and Bender[38] for further details of the interconversion factors.
[b] There are a large number of isomeric forms of vitamin E; only the more common ones are listed here.
[c] Vitamins D_3 and D_2 are equipotent for humans, but not for other mammals.

other potential problems in interpreting and comparing vitamin status indices are further discussed in section 5.

2 HISTORY

During the latter half of the nineteenth and first half of the twentieth century, most of the vitamins that are now recognized as being essential dietary components were isolated, crystallized, identified and then synthesized, and the methods used were the standard organic chemistry techniques that were then available or being developed, such as solvent partitioning, fractional crystallization, paper and thin-layer chromatography (TLC), GLC and so on. For some of the vitamins, physicochemical techniques (such as fluorimetry) and the formation of chemical derivatives with characteristic absorption or fluorescent spectra, were used for the identification and analysis. With the opportune discovery that many of the vitamins (especially in the B-group) were essential for the growth of particular microorganisms in purified growth media, it became possible to select particular species and strains of microorganisms which, with defined media which lacked a particular vitamin, could be used to quantitate that vitamin in liquid samples or in tissue extracts of biological origin. Gradually a wide range of assay techniques became available, which were tailored to the analysts' particular requirements, so that the food vitamin assay procedures then gradually diverged from those used for status assays or for pharmaceutical preparations. A brief selection of some historically important methods for the individual vitamins is listed below.

For the fat-soluble vitamins (A, E, D, K) and for vitamin C, the bioassay methods that were developed were in animals, generally based on growth stimulation in rodents such as rats or guinea pigs, or in chickens. Bioassay procedures for vitamin A,[17] E,[18] D,[19] and K[20] were of this type; that for vitamin D depended on X-ray pictures of bone growth (line test) and that for vitamin K depended on tests of the efficiency of the blood clotting process. Early procedures for the spectrophotometric assay of vitamin A in tissue extracts depended on the use of Lewis acids, such as antimony trichloride or trifluoroacetic acid,[21] which gave a transient colored product. Vitamin E could be assayed by virtue of its ability to protect against oxidative haemolysis of red blood cells.[22] Vitamin K status can be investigated by a variety of tests of the integrity of the blood clotting cascade which constitute specific functional tests of vitamin K status.[23] Vitamin C was originally measured by animal assays,[24] but a number of semispecific chemical assays were also developed at an early stage, based on the powerful reductive potency of vitamin C, or the formation of fluorescent derivatives or of colored osazones, after oxidation.[25]

Most of the B vitamins can be measured by specific microbiological assays,[26–33] and many of these are still in use, especially for food analysis, because they can usually cope with a multiplicity of different forms of each vitamin. However, the extraction and assay conditions require careful attention to detail[1] and there remain some serious problems of disagreement between different laboratories about the procedures.[30] For some of the B-vitamins, fluorimetric assays have been developed.[34,35] and there are protein-binding RIAs for folate and vitamin B_{12}.[36,37] Some of these have been developed for status assays, others are more suitable for foods and feeds. As clinical chemistry laboratories have developed a need for vitamin status assays, commercial kits have been developed, whose emphasis has been on simplicity, speed of use and high throughput, in contrast to the older assays, which were slow and time-consuming (but which in some cases were nevertheless more reliable than their modern counterparts).

3 FAT-SOLUBLE VITAMINS

3.1 Vitamins A, E and Carotenoids in Serum, Plasma and Breast Milk

Most clinical and epidemiological investigations of vitamin A status rely on the direct estimation of vitamin A in serum or plasma. Because many of the vitamin A assays that have been developed recently can also measure vitamins E and carotenoids, this group of analytes is generally measured in a combined assay, using high-performance liquid chromatography (HPLC) to separate the individual components and a variety of detection methods (optical density, fluorescence or electrochemical reaction: Table 4). Serum or plasma vitamin A concentrations reflect body stores only when the latter are severely depleted (liver concentration $< 70\,\mu mol\,kg^{-1}$, plasma concentration $< 0.7\,\mu mol\,L^{-1}$). When the liver stores are greater than $70\,\mu mol\,kg^{-1}$, plasma concentrations are largely independent of them. Serum or plasma concentrations that are considered to be either low ($<0.7\,\mu mol\,L^{-1}$) or deficient ($<0.35\,\mu mol\,L^{-1}$) occur more commonly in young children than in adults, and most commonly in poorer countries, where good dietary sources of preformed vitamin A from animal foods, or dietary supplements and of rich sources of precursor carotenoids from fruit and vegetables are unavailable. Poor maternal status can arise during pregnancy and lactation in those countries where dietary sources are inadequate, and the concentration of vitamin A in breast milk (expressed as a ratio to the fat content) may

Table 4 Currently used vitamin status assays

Vitamin	Concentration assay	Sample type	Functional assay	Sample type	Comments
A	Retinol by HPLC (optical density or fluorescence detection)	Serum or plasma	Relative dose response test; Conjunctival impression cytology	Serum or plasma. Goblet cells from conjunctiva	Most clinical and epidemiological studies measure plasma concentration
Carotenoids (including several vitamin A precursors)	Individual carotenoids by HPLC (optical density, fluorescence or electrochemical detection)	Serum or plasma	N/A	–	Usually now included with vitamin A assay
E	Tocopherols by HPLC (optical density, fluorescence or electrochemical detection)	Serum or plasma	Oxidative lysis of erythrocytes	Erythrocytes	Concentration assay is usually combined with vitamin A and carotenoids
D	25-Hydroxy vitamin D by HPLC or RIA	Serum or plasma	(Seldom used)	–	RIA available as a commercial kit assay
K	Phylloquinone and menaquinones by HPLC (fluorescence or electrochemical detection)	Serum or plasma	Blood clotting assays; PIVKA	Whole blood; plasma	Concentration assay confined to specialist laboratories. Clotting assays are less complex but also less specific
C	Ascorbic and dehydroascorbic acids by HPLC (various detectors) or by direct assays w/o separation	Serum or plasma; buffy coat	N/A	–	Buffy coat assay is a better index of body stores, but is more complex and seldom performed now
B_1 (thiamin)	Total thiamin by direct fluorimetric assay, or HPLC with fluorescence detection.	Urine	Transketolase (activation coefficient)	Erythrocyte lysates	Transketolase is most commonly used but is difficult to standardize
	Thiamin diphosphate by HPLC.	Red cells			
B_2 (riboflavin)	Total riboflavin by direct assay or HPLC; fluorimetric detection	Urine	Glutathione reductase (activation coefficient)	Erythrocyte lysates	Glutathione reductase is most commonly used
B_6 (pyridoxine)	Pyridoxal phosphate or total B_6 by HPLC	Plasma	Aspartate amino-transferase (activation coefficient)	Erythrocyte lysates	Wide variety of assays used; no general consensus on preference
	Pyridoxic acid: HPLC	Urine			
Folate	Total folate	Serum or plasma	Various (e.g. polymorph lobe counts, formimino glutamate, homocysteine)	Various	Serum folate is most commonly used; red cell folate is a better measure of stores
	Total folate	Red cells			

(*continued overleaf*)

Table 4 (*continued*)

Vitamin	Concentration assay	Sample type	Functional assay	Sample type	Comments
B_{12} (cobalamin)	Vitamin B_{12} by protein-binding or microbiol assay	Serum	MMA	Serum or urine	Combination of serum B_{12} and MMA is recommended
Niacin	Niacin metabolites (N^1-methyl nicotinamide; pyridones) by fluorimetry/HPLC.	Urine	N/A	–	Not often required, therefore not widely available
	Pyridine nucleotides in whole blood	Whole blood			
Biotin	Total biotin by protein-binding or microbiological assay	Serum	Lymphocyte propionyl CoA carboxylase (activation coefficient)	Lymphocytes	Not often required, therefore not widely available
Pantothenate	Total pantothenate by microbiological assay	Serum	N/A	–	Not often required, therefore not widely available

MMA, Methyl malonic acid; PIVKA, protein induced by vitamin K absence.

be a better index of maternal intakes and status than blood levels are.[39] Unfortunately the breast milk content varies considerably with stage of lactation, so its interpretation can be complex. Because vitamin A can be toxic at very high intakes (e.g. more than ten times the recommended intake taken regularly, or more than a hundred times the recommended intake taken intermittently), there may also be a need to investigate plasma or serum levels for evidence of overload. In this situation the concentration of retinyl esters, especially in the chylomicrons, is greatly increased so that the ratio of retinyl esters to retinol (which is normally very low), rises dramatically.

Vitamin E occurs in blood plasma or serum in a variety of different forms (reflecting the varying composition of different dietary sources), of which all-rac D-α-tocopherol is the most biologically potent (Table 3), and is usually the most prevalent form. Although modern HPLC-based (and similar) assay procedures can easily separate and quantitate each of the individual forms of the vitamin, this degree of detail is seldom necessary for the definition of normal ranges. However, it has been found to be preferable to judge status on the basis of vitamin E: lipid ratios rather than of vitamin E concentrations per unit volume, because of the strong covariance of vitamin E with lipid levels. Severe deficiency is associated with vitamin E concentrations below 1.1 μmol g^{-1} total plasma lipid, or below 2.2 μmol mol^{-1} cholesterol, but it has not yet proved possible to define an optimum concentration for long-term protection against peroxidative damage. Unlike vitamin A, vitamin E concentrations are not constrained by a specific binding protein and plasma levels are approximately proportional to intakes over a wide range. Overt toxicity has not been reported, even at very high intakes.

Like vitamin E, plasma carotenoid concentrations are approximately proportional to dietary intakes over a wide range; they are concentrated in the lipidic components of plasma or serum and most of them are generally considered to be nontoxic over a wide range of intakes. α- and β-Carotenes and the cryptoxanthins are partially converted to vitamin A within the intestinal wall and in other tissues, and are therefore useful contributors to vitamin A stores, especially for people whose diets do not contain animal products or dietary supplements, and therefore lack preformed vitamin A. Other dietary plant carotenoids, such as lycopene and the xanthophylls (lutein, zeaxanthin) are not precursors of vitamin A in humans, but most of the carotenoids are thought to possess useful antioxidant properties and are therefore of potential health significance with respect to the limitation of free radical-generated tissue damage. As noted earlier, they are not classified as vitamins per se, but because some of them are vitamin A precursors, because they are potentially protective, because they can provide an index of fruit and vegetable consumption and because they can be measured in conjunction with vitamin A and E, they are generally included in the assay procedures and protocols for these vitamins, especially in the context of epidemiological studies of population vitamin status.

Examples of modern assay procedures for vitamin A in serum, plasma, milk and tissues can be found in the literature.[40–73] Some of these also include simultaneous procedures for vitamin E and/or the carotenoids. Other aspects of the analytical methods and status determination issues for vitamin E have been

described.[74–90] Reviews that concentrate particularly on these vitamins are by Davidek and Velisek,[4] De Leenheer et al.,[6] and Furr et al.[52] In the author's laboratory, a minor modification of method given by Thurnham et al.[47] has been in constant use for several years, and has proven to be robust, precise and accurate for the analysis of vitamins A and E and seven carotenoids in human plasma samples for survey work.

Some interesting new developments, which have not yet been widely adopted, include the use of retinoic acid as an alternative index of vitamin A status,[41] the use of oxidation product(s) of vitamin E as an alternative index of vitamin E states,[74] the use of CE for the separation of fat-soluble vitamins before detection[50,53,91] and the use of MS to assist in the specific recognition of these vitamins or the use of stable isotopes for recovery assessment.[44,60,62,68,69,73,82,92] Vitamin E and its oxidation products have been assayed in the cellular components (membranes) of the blood.[77,80]

In the USA, there is an EQAS for these analytes, run by the National Institute of Standards and Technology (NIST) (Micronutrients Measurement QA Program, NIST, Gaithersburg, MD 20899, USA; fax: +1 301 977 0685; e-mail: jbthomas@nist.gov). In the UK, an equivalent scheme is run by Ms Maureen Goodall, tel: +44 981 296 2804; fax: +44 181 641 2633.[a]

3.2 Vitamins A, E and Carotenoids in Foods and Pharmaceuticals

The assay procedures used for these vitamins in foods overlap considerably with those used for status assays, the main differences residing in the extraction procedures, which are necessarily more complex than those needed for blood analysis, partly because the food matrix is much more variable and complex, and partly because the liberation of the free vitamins from their fatty acid esters by saponification is usually an essential part of the food analysis procedure, whereas in blood serum or plasma, most of them are present in unesterified forms.

Bioassays for these nutrients were the precursors, and in a sense the gold standards, for the later physicochemical-type assays. They bridged the gap between the functions of the vitamins, as essential components of the diet (of humans and animals) for their survival and health, and the identification of their unique chemical structures and detailed biochemical functions, which permitted the development of more sophisticated and more rapid assays, based on their physicochemical properties. For vitamin A, and for its precursor carotenoids, the carotenes and the cryptoxanthins, the animal bioassays depended on growth rate (in rats), a vaginal smear test (correction of keratinization in vaginal smears in ovariectomized rats) and a liver vitamin A accumulation or storage assay, which measured the amount of vitamin A accumulated after a predetermined dietary amount of the test food.[1] These bioassays were able to test the relative potencies of different vitamin A precursors, but only with respect to their potencies in rats, which may differ from those in humans. Analogous bioassays have also been used for vitamin E. Three approaches that have been used successfully are the foetus resorption test in vitamin E-deficient rats, an erythrocyte peroxidative haemolysis test in deficient rats and a liver-storage test in rats or chicks.[1]

Saponification of food homogenates before extraction is classically performed by heating with potassium hydroxide, frequently with the additional of methanol or ethanol (which helps to denature the proteins) and frequently with antioxidants such as pyrogallol, butylated hydroxytoluene (BHT) and so on. Extraction uses nonpolar solvents such as diethyl ether, hexane, tetrahydrofuran, acetonitrile and so on.

HPLC separation of vitamin A, E (multiple forms) and carotenoids in food extracts is similar, in principle, to that described in section 3.1, except that the range of components is likely to be more complex. Gradient elution with complex mixtures of solvents may be needed. Several examples[49,71,75,93–106] may be added to those listed elsewhere.[1,4,5,11]

The assay of vitamins A, E and carotenoids in pharmaceutical preparations is similar in principle to that in foods, but because the concentrations are higher and the complexity of the material is less, the analytical task is less demanding. HPLC is the preferred technique, but a simpler assay, based on optical density or fluorescence, may be feasible for some types of preparation.[67,106]

3.3 25-Hydroxy and 1,25-Hydroxyvitamin D in Serum, Plasma and Breast Milk

Vitamin D shares with several other vitamins the property that a dietary source of the preformed vitamin is not the only biological source of the vitamin. It is, however, the only vitamin that is formed by the action of sunlight on a precursor within the skin, and it is the extent of exposure to ultraviolet (UV) light (of a limited range of wavelengths), rather than the amount of the precursor present, which is critical for the amount of de novo formation. Because of this, wide natural variations in the amount of exposure to sunlight (latitude, season and clothing) are critical in determining whether sufficient vitamin D is produced de novo, or whether food sources are essential, in order to achieve adequate status and freedom from the classical vitamin D deficiency diseases: rickets and osteomalacia. Status is measured

[a] All contact details correct May 1999.

biochemically by blood analysis and there are two principal and important circulating forms of the vitamin: 25-hydroxyvitamin D and 1,25-hydroxyvitamin D. The 25-hydroxy form reflects the sum of the contributions to the vitamin from food and from the action of UV light on the skin, and this is the analyte that is normally used to define biochemical status. However, the 1,25-dihydroxy form is the active functional (hormone-like) metabolite, whose concentration indicates biological efficacy, so that measurement of this metabolite may also be necessary if there are biological or pathological reasons why the interconversion pathway(s) might be disrupted. The principles behind these metabolic processes and the practical choices for the status analyst, are discussed in greater detail in several reviews.[107–111] Although the measurement of vitamin D per se is important for food analysis and for the study of tissues other than blood, its value as a clinical status index is limited.

There are many published methods for 25-hydroxy-vitamin D based on HPLC. A selection of publications is listed.[112–117] Somewhat simpler procedures, with a more rapid throughput rate, have been developed on the principle of specific binding proteins or specific antibodies to synthetic analogues of the naturally occurring vitamin, which generally require a radioactively labeled form of the vitamin as a marker of the extent of binding and hence of the concentration of the unlabeled analyte in the biological sample extract.[118–129] Although the outcome of independent assessment of RIA-based commercial kit assays has not always been favorable,[130] in the author's laboratory this choice of assay has proved adequate for survey work requiring long-term reproducibility and procedural simplicity.[129] There have been several studies using MS[131,132] and some studies of hydroxylated derivatives of vitamin D other than the well-known 25-hydroxy and 1,25-dihydroxy vitamin D.[115,133] An EQAS in the UK for serum or plasma is run by Mr Graham Carter, DEQAS, QA Working Party, Charing Cross Hospital, London W6 8RF, tel: +44 181 846 7074; fax: +44 181 846 7009; email: g.carter@cxwms.ac.uk.

For lactating mothers, the concentration of vitamin and its hydroxylated metabolites varies with the status of the mother. The measurement of breast milk concentrations[39,116,134] can therefore provide additional status information.

3.4 Vitamin D and its Derivatives in Foods and Pharmaceuticals

There are two main forms of vitamin D in foods: vitamin D_3 (cholecalciferol), which is derived (in vertebrates) from the action of sunlight on 7-dehydrocholesterol, and vitamin D_2 (ergocalciferol), which differs only in the presence of a double bond at C-22–C-23. Vitamin D_2 is derived from ergosterol, which is found in plants, fungi and invertebrates. There are smaller amounts of the 25-hydroxy derivatives of those compounds, present in some animal tissues, and there may be significant amounts of previtamin D_3, which is the intermediate between 7-dehydrocholesterol and vitamin D_3 and possesses about half of its antirachitic activity in experimental animals.

The older, but still potentially useful, bioassay for vitamin D activity of foods is the ''rat line test'', which measures the potency of the test substance to induce new calcification in the tibia, radius or ulna of a vitamin D-deficient rat, and hence to form a deposit of silver after staining with silver nitrate (the silver nitrate is converted to silver phosphate by reaction with the deposited calcium phosphate, and then to metallic silver by photochemical reduction).

Modern assay procedures depend on HPLC after saponification (if necessary, to remove triglycerides), extraction into a nonpolar solvent, evaporation and re-solution in the mobile phase. Preliminary cleanup procedure(s), such as solid-phase extraction, are likely to be necessary before the analytical separation and quantitation. Both normal-phase and reversed-phase HPLC systems have been used; representative selections of these have been reviewed.[1,5,11] As with the other fat-soluble vitamins, pharmaceutical preparations can be assayed by similar procedures, but simpler alternatives may be appropriate.[67,106]

3.5 Vitamin K in Serum, Plasma and Breast Milk

Until quite recently, the technical difficulties associated with the measurement of vitamin K (phylloquinone and menaquinone) contents of body fluids were such that status measurements had to depend on indirect measurements, or ''functional'' indices, such as the efficiency of blood clotting in vitro, or the accumulation of undercarboxylated blood proteins which were specifically caused by a lack of vitamin K (e.g. PIVKA), and most recently by undercarboxylated osteocalcin.[135] These are extremely sensitive and valuable status indices, but for some purposes, such as the comparison of dietary vitamin K intakes with blood vitamin levels, it has become necessary to develop the analysis of vitamin K per se in serum, plasma and breast milk. (The last was especially important because breast-fed babies are at relatively high risk of vitamin K deficiency, and a variety of interventions have been devised to decrease this risk, including the provision of vitamin K supplements for nursing mothers to raise their breast milk levels.)

Because of the low concentration of vitamin K in body fluids and the lack of a specific and sensitive physical property, chemical derivatization process or RIA, its quantitation required the development of highly efficient HPLC assays, usually with at least two sequential

separation stages, to achieve an adequate purity and a high enough concentration for accurate quantitation by fluorimetry or electrochemical detection.[135–146] Some of these procedures have focused specifically on vitamin K_1 (alias phylloquinone: the principal form of vitamin K that is present in plant foods); others have included the measurement of the series of menaquinones from bacterial sources that share vitamin K activity, although the relative biopotencies are not known precisely.[137,139,147–149] Phylloquinone has also been quantitated by a stable isotope-dilution gas chromatography/mass spectrometry (GC/MS) assay.[150] Tissue assays have been developed for experimental metabolic studies in humans and animals.[136,147,149,151,152] After many years in which its relevance for human nutrition was largely ignored, the importance of adequate intake and status has recently received attention, which is reflected by the greatly increased numbers of publications.

An EQAS for vitamin K assays has recently been made available in the UK: Dr Alison Cox or Dominic Harrington, Haemophilia Centre, St Thomas' Hospital, London SE1 7EH, tel: +44 171 928 9292; fax: +44 171 401 3125.

3.6 Vitamin K in Foods and Pharmaceuticals

Assays of vitamin K in foods should include both phylloquinone and the menaquinones of bacterial origin. Since good physicochemical assays for this vitamin have only recently become available (and most food table compilations do not yet have values for vitamin K because its content in many foods is not known accurately), the availability of a bioassay has been critically important. The most commonly used procedure depends on the increase in blood clotting time that is observed in young chicks after feeding a vitamin K-deficient diet, and the fact that test substances containing vitamin K will reduce this clotting (prothrombin) time, towards the normal value.

Because vitamin K is destroyed by strong alkali, the removal of triglycerides before extraction requires enzymatic hydrolysis. Vitamin K can be extracted into nonpolar solvents or into supercritical (liquid) carbon dioxide. HPLC can be of the normal or reversed-phase type and the preferred detectors are of the fluorescent or electrochemical type, since these are both more sensitive and potentially more specific than the standard optical density type for substances like vitamin K. Examples of procedures developed between 1988 and 1998 have been described.[1,5,11]

4 WATER-SOLUBLE VITAMINS

4.1 Vitamin C in Serum, Plasma, White Cells, Urine and Breast Milk

In principle, the measurement of vitamin C concentrations and status should be easier and more straightforward then that of some other vitamins, because it is present at higher concentrations and has a characteristic reducing activity, which can be harnessed on the basis of colorimetric assays linked to redox dyes. In practice, however, the task of devising accurate and reliable vitamin C status assays has proved difficult, partly because of its rapid oxidative degradation in solution and partly because of interference by other components of body fluids, tissues, foods and so on. Since the early studies on vitamin C and scurvy which relied on animal bioassays, there have appeared dye-reduction methods, methods linked to transition-metal-ion reduction, methods linked to the formation of colored osazones with dinitrophenylhydrazine, methods linked to the formation of fluorescent adducts with orthophenylene diamine, HPLC methods with optical density, fluorescence or electrochemical detection, GC of volatile derivatives and GC/MS methods.[153,154] With the advent of user-friendly HPLC apparatus, this approach now tends to be favored[155–174] because it is reasonably specific and is less subject to interference, especially if combined with a relatively specific detector, such as the newer electrochemical or coulometric devices.[156,161,162,164,166,168,170,173,175]

Because of the problem of rapid degradation, it is essential that vitamin C be preserved efficiently in the samples that are collected, either by acidification with a chelating acid or by adding a reducing agent, which must not interfere with the assay-detection system. A variety of alternative procedures have been described.[160,167,176–179] With care, it is possible to preserve samples for more than a year at low temperatures and with suitable stabilizing agents.

In the author's laboratory, a fluorescence-based assay in a centrifugal analyzer[180] has proved satisfactory for plasma vitamin C analysis in survey samples, and this technique compares consistently well with more time-consuming HPLC-based assays. Vitamin C assays have begun to utilize CE[181–183] and GC/MS is also proving to be a powerful alternative for certain specific tasks and for method validation.[154,184,185] The NIST QA scheme, described for vitamins A, E and carotenoids, also runs a plasma vitamin C QA scheme.

Today, vitamin C status is usually measured by serum or plasma concentrations, which vary between undetectable levels in depleted subjects, up to concentrations around 100 μM in people with a generous intake. For several decades, however, there was a preference for the use of buffy coat (total white cell) vitamin C, which was shown, in animal models, to be a more accurate reflection of whole body status. This has now fallen into disfavor, partly because the fieldwork procedures are complex and time-consuming and partly because the result is very sensitive to variations in the proportions of the different types of white cells in the buffy coat, which in turn is affected by infections and so on. Serum or plasma

concentrations of vitamin C (and of other water-soluble vitamins) are sensitive to recent dietary intakes of rich food sources or supplements, but this potential problem can be minimized by collecting the blood sample after an overnight fast. The concentration of vitamin C in urine is less useful as a status indicator, partly because of instability (which varies with pH and other urinary constituents), and partly because it varies with variations in kidney function. Breast milk vitamin C concentrations do vary with variations in status,[39] but they are rarely used to investigate it, partly because the range is narrower than that in plasma.

4.2 Vitamin C in Foods and Pharmaceuticals

There are several potential problems that can complicate the assay of vitamin C in foods. First, some foods in some countries may contain the unnatural isomer of L-ascorbic acid: D-erythorbic acid or D-isoascorbic acid, which may be added, especially to cooked meats, as a color preservative and to reduce the formation of carcinogenic nitrosamines from the nitrite (which is added as an antimicrobial agent). The D-isomer of vitamin C has very similar chemical properties to those of ascorbic acid, but it has little of its biological potency because it is poorly absorbed and is rapidly excreted. Therefore, a separation of the two isomers (generally by HPLC) is necessary if the D-isomer is present. Second, as noted earlier, ascorbic acid is easily oxidized, especially in the presence of transition-metal ions; therefore its extraction into a preservative medium and subsequent analytical steps must be performed with careful attention to antioxidant precautions. Most extracts of foods contain a significant proportion of the oxidized but biologically active form of the vitamin, dehydroascorbic acid, which may be present in the native food per se, or which may be formed by oxidation during the extraction procedure. This must be included in the final assay. There are many variants of food vitamin C assays described in the literature. Rich sources of the vitamin without interfering substances can be assayed by several relatively simple physicochemical assays (e.g. the measurement of dye reduction), but less-rich sources generally require more complex assay procedures.

Bioassay procedures for vitamin C are cumbersome and time-consuming: they are generally based on the rate of maturation of the odontoblast cells in the incisor teeth of guinea pigs who have been receiving a diet which is deficient in vitamin C. It is necessary to use guinea pigs, because most other species, (other than humans and the higher primates), can synthesize vitamin C de novo from sugars and do not require a dietary source of the vitamin.

For physicochemical assays of the vitamin, extraction into a chelating acid is required and this should typically be metaphosphoric acid, or a mixture of metaphosphoric and acetic acids. For those extracts that can then be assayed without further separation, the choice lies between the classical reaction with 2,6-dichlorophenol indophenol, or a related dye, which is stoichiometrically decolorised by the reductive action of vitamin C, provided that all of it is present in the reduced form. A wide variety of reducing agents cause positive interference in this assay, however. Another relatively crude assay, which is only adequate for some fruit drinks or pharmaceutical preparations, is the measurement of the optical density at 267 nm (pH 6.0), before and after the copper-catalyzed oxidation of the vitamin. A more specific fluorometric assay, which has the advantage that it includes both ascorbic and dehydroascorbic acids because the former is deliberately oxidized to the latter, depends on the reaction of dehydroascorbate with *o*-phenylene diamine to give a fluorescent quinoxaline (see section 4.1). Several methods have been used to convert ascorbic acid to dehydroascorbic acid in this assay; the most specific is ascorbate oxidase enzyme, isolated from certain plants. A semiautomated version of this assay was adopted by the Association of Official Analytical Chemists (AOAC) for the determination of vitamin C in foods in 1990.[186]

HPLC has undoubtedly become the most reliable procedure for vitamin C analysis, especially as it is the only technique (of those that are widely available) that can distinguish between the D- and L-isomers of the vitamin. In addition, it is possible to measure dehydroascorbate by running the assay with and without a reducing agent, used to convert the dehydro form to the reduced form. Detection can be achieved by optical density, or preferably by electrochemical (or coulochemical) detection, the latter being considerably more sensitive and specific. Column types can be weak anion exchange, or ion exclusion, or reversed phase, preferably with an ion-pairing agent, usually an organic amine, with suitable precautions to avoid the precipitation of metaphosphate salts on the column. A large number of alternative procedures have been described.[1,11,175] In addition, CE methods have been developed,[1,181,183] and GC/MS has also been described.[187] The use of guaicol peroxidase as an alternative to ascorbate oxidase for the specific oxidation of ascorbic acid in a crude spectrophotometric assay has been described and a variety of flow injection analyses, some of which employ immobilized enzymes, have been reported.[1] These and other simplified procedures.[67,104] are likely to be suitable for many types of pharmaceutical preparation with relatively high concentrations of the vitamin.

4.3 Thiamin (Vitamin B_1) Indices in Blood, Urine and Breast Milk

For many years, the assessment of thiamin status was principally by urine analysis,[2] and was based on the

principle that thiamine could be oxidized completely to the fluorescent derivative, thiochrome, by alkaline ferricyanide treatment. This provided a reliable and sensitive measure of status in individuals and populations with relatively generous intakes of the vitamin, because the excess of intake over requirements was almost quantitatively excreted in the urine. In severely depleted or partially depleted subjects, however, the test was less discriminatory. For this and other reasons, including the difficulty of collecting an accurately timed urine sample, the enzyme reactivation test based on red cell transketolase activity was developed by Brin, described by Sauberlich et al.[2] and Bates.[16] This depends on the principle that with progressive tissue thiamin depletion, certain thiamin cofactor-dependent enzymes such as red cell transketolase become progressively depleted of their essential cofactor and therefore lose enzyme activity. Addition of the missing cofactor in vitro restores at least some of the lost activity. The extent of depletion and hence tissue status can be estimated in terms of the ratio of reactivated to nonreactivated enzyme activity, in vitro. The advantages of this approach are that it is highly sensitive to status variations in the critical range of moderate-to-severe depletion, and because it depends on a ratio of two enzyme activities, any procedural variations that may affect the absolute activities (pH, temperature, assay components and so on) are less important than they would be for activity measurements per se.

Although the measurement of thiamin status by the red cell transketolase activation coefficient has been widely used especially in population surveys,[188] it does have some disadvantages, notably that the cofactor-depleted apoenzyme is slowly destroyed in vivo, that the red hemolysates needed for the assay need careful preservation before the assay and that there are no EQAS, or well-established validation procedures, for the assay. Direct thiamin assay procedures have been improved and made gradually more sophisticated since the late 1970s.[189–205] Many of these have made use of recent advances in HPLC[191,194–205] and the measurement of blood or red cell concentrations of thiamine phosphate esters has thus become an attractive alternative to the existing status assays.[191,193,194,197–205]

The thiamin content of breast milk does not reflect maternal status to a degree that can make it useful as a status assay,[39] and other functional assays of thiamin status have generally proved too cumbersome and not sufficiently reliable for widespread adoption.

4.4 Thiamin (Vitamin B_1) in Foods and Pharmaceuticals

Thiamin is present mainly as the cofactor, thiamin diphosphate or thiamin pyrophosphate (TPP) which is noncovalently bound to apoenzyme protein. It can be extracted without loss of vitamin activity at acid or neutral pH, but in alkali it is easily destroyed by oxidation. Indeed, one of the most commonly used assay procedures relies on its oxidation to the inactive product, thiochrome, by alkaline ferricyanide. It can also be inactivated by UV irradiation or exposure to sulfite, which cleaves apart the two halves of the molecule. Extraction from foods is achieved either by heating with dilute (0.1 N) hydrochloric acid, typically at ca. 108 °C for plant foods such as cereals, or at 121 °C for animal foods, or by treatment with wide-spectrum proteolytic enzymes, e.g. those of fungal (diastase) and plant (papain) origin.

The soluble extracts that are obtained by these extraction procedures can be assayed either by microbiological growth assays (*Lactobacillus fermentum* or *L. viridiscens*), or by fluorimetric assays, which may or may not require HPLC separation to achieve an initial purification of the vitamin. AOAC fluorimetric assays of thiamin in food extracts rely on open column chromatography followed by a simple extraction of the oxidation product, thiochrome, into butan-2-ol, before the measurement of its fluorescence. HPLC-based methods have been devised, which either separate thiamin and then convert it to thiochrome in a postcolumn reaction, or which oxidize the thiamin in a precolumn reaction and then separate the thiochrome before fluorimetric quantitation. Examples of these two alternative approaches are listed.[1,11,191,192,206–212] GC separation has also been employed.[4,11,213] Assay of thiamin in pharmaceutical preparations.[67,106] is relatively straightforward.

4.5 Riboflavin (Vitamin B_2) Indices in Blood, Urine and Breast Milk

As with thiamin, the earlier studies of riboflavin status and requirements depended on the measurement of urinary excretion, preferably in a timed urine sample.[2] This procedure has similar limitations to those encountered for thiamin, and as a test of status it has now largely been replaced by the red cell glutathione reductase test.[16,214] Like transketolase for thiamin status, glutathione reductase in red cells loses its riboflavin-derived cofactor, FAD, progressively during tissue riboflavin depletion, and the extent of this depletion is accurately reflected in the ratio of reactivated to nonreactivated enzyme activity in vitro. The activation coefficient, which is the ratio of reactivated to nonreactivated enzyme activities, increases from 1.0 (no difference) in a fully replete subject, to values well above 2.0 in severe deficiency. The normal range is usually deemed to be from 1.0 to 1.3 or 1.4, depending on the details of the assay procedure. This test has proven to be rugged and reliable; it is adequately discriminatory for population studies and it has been widely used and adopted. Nevertheless, the problems that exist for the

transketolase test are also true to some extent for the glutathione reductase test and there remains a need for concentration-type assays.

Riboflavin and its esters can be assayed by a wide range of techniques. Advances in urinary riboflavin assays have been described.[215–217] Other developments, such as luminometric assay[218] and competitive-binding assay, based on specific binding proteins have also been described.[219–222] HPLC assays[216,223–227] and enzyme-based assays have been described.[228,229] Clearly there is now a wide range of choices and the particular selection will depend on the particular application.

Unlike thiamin, the riboflavin content of breast milk could be a moderately useful indicator of maternal status,[39] although it has not often been used for this purpose.

4.6 Riboflavin (Vitamin B_2) in Foods and Pharmaceuticals

Riboflavin is relatively stable to heat and to variations in pH, except when exposed to light, when it is rapidly and irreversibly degraded. The product of light-catalyzed degradation in alkaline solution is the highly fluorescent compound, lumiflavin or 7,8-trimethylisoalloxazine, and this forms the basis of the majority of nonbiological assay procedures for riboflavin. In foods, the vitamin occurs as free riboflavin, as riboflavin phosphate (FMN) and as the more complex enzyme cofactor FAD. There are also forms of riboflavin that are covalently bound to certain enzymes, but these are generally unavailable as food sources of the vitamin.

Like thiamin, riboflavin is usually extracted from foods by hot dilute mineral acids such as 0.1 N hydrochloric acid, typically by autoclaving at 121 °C, which converts FAD to FMN. Enzyme preparations such as fungal diastase are used, especially if complete conversion of FMN to riboflavin is required.

Microbiological growth assays have been widely used for the quantitation of riboflavin in food extracts, typically *Lactobacillus casei* (rhamnosus) or *Enterococcus faecalis*. Removal of lipids may be necessary to avoid interference in the assay. The principal physicochemical approach to riboflavin assay relies on fluorimetry, with or without HPLC separation. For rich sources of riboflavin, simple cleanup procedures and a suitable assay blank will permit quantitation without chromatographic separation, but HPLC-based assays have been gaining acceptance.[1,11,206,212,224,230–238,239] Extracts are likely to contain both free riboflavin and FMN and these have different fluorescence response factors which must be taken into account. Riboflavin can easily be assayed by its fluorescence in extracts of pharmaceutical preparations.[67,106]

4.7 Vitamin B_6 Indices in Blood, Urine and Breast Milk

Vitamin B_6 occupies a somewhat paradoxical and atypical position, in that severe and overt deficiency is hardly ever encountered (it is not a characteristic of poor quality third world diets), yet it remains a potential problem for optimal nutrition, because evidence from several sources indicates that the ratio of this vitamin to other dietary components, particularly to protein, may be suboptimal for many human populations. A variety of assays for the vitamin itself or its degradation products (notably pyridoxic acid), and a variety of functional status assays have been proposed and developed.[16] Among the latter are the pyridoxal phosphate-dependent glutamate and aspartate aminotransferases that occur in red blood cells. Enzyme reactivation assays with pyridoxal phosphate in vitro have been developed which are analogous to the transketolase assay for thiamin status and the glutathione reductase assay for riboflavin status. In competition with this approach is the direct measurement of several forms of vitamin B_6, or of pyridoxal phosphate, in serum, plasma or whole blood samples.[239–252] Although HPLC separation and fluorimetric detection have been widely used for the measurement of vitamin B_6 in blood,[239–247,249,254] the use of a pyridoxal phosphate-requiring enzyme, stripped of its cofactor, such as tyrosine decarboxylase apoenzyme, has been used,[253] and offered as a commercial kit assay for the measurement of pyridoxal phosphate and hence of vitamin B_6 status. The use of microbiological assays for vitamin B_6, which were used for status measurements in early studies, and which remain a mainstay of food vitamin B_6 analysis, are not commonly used for status measurements now, being too cumbersome and incompatible with modern clinical laboratories.

Unfortunately there is poor agreement between the different indices of vitamin B_6 status, each of which is prone to a different set of confounding factors which can complicate the interpretation of vitamin B_6 status. There is some ongoing research that may resolve these problems. Meanwhile it is probably advisable to use a combination of several status indices if possible. Breast milk vitamin B_6 concentrations vary with variations in maternal vitamin B_6 intake,[39] but are seldom used to determine status.

There are a number of functional indices of vitamin B_6 status which focus on specific intermediates of amino acid turnover, but these are of research interest, rather than being in routine use, e.g. for surveys.

4.8 Vitamin B_6 in Foods and Pharmaceuticals

Vitamin B_6 occurs in several different forms in foods. In unfortified foods the principal forms are pyridoxal,

pyridoxal phosphate, pyridoxamine phosphate and pyridoxine glucosides; fortified foods may also contain pyridoxine. Some of these forms are tightly bound to protein, and the sensitivity of vitamin B_6 to light-catalyzed degradation requires the use of rigorous precautions to exclude short-wavelength light during the analytical procedures. A major degradation product, formed from pyridoxal phosphate in vitro is the fluorescent pyridoxic acid 5′-phosphate, which is biologically inactive. The pyridoxine glucosides that occur in considerable amounts in plant tissues have a lower biological potency than the nonglucosidic forms of the vitamin, further complicating the relationship between the analytical values and the vitamin potencies of native foods.

Generally, foods are first treated with mineral acids such as dilute hydrochloric acid, under autoclave conditions, to release vitamin B_6 from the food matrices. If more detailed information is required about the forms that are present in the native foods, then an extraction at low temperatures with protein denaturants such as trichloracetic, metaphosphoric acids and so on, may be preferable. Treatment with β-glucosidase can be used to release pyridoxine from the glucosides and to measure the percentage of glucosylated vitamin present in the food. Other enzymes, such as proteases, have also been used to achieve gentle release of the vitamin from the food matrix.

Microbiological growth assays of vitamin B_6 in food extracts have used yeasts, *Saccharomyces carlsbergensis* (uvarum) or *Kloeckera apiculata*, and these have been used alone, or in combination with partial cleanup procedures, or chromatography. Fluorimetry, with or without HPLC separation has also been used and a range of procedures have been described.[1,11,104,241,242,244,254] Procedures for pharmaceutical preparations are also available.[67,106]

4.9 Folate Indices in Blood, Urine and Breast Milk

The measurement of folate status, together with that of vitamin B_{12}, has for many years been a standard function of those routine hematological laboratories which include ''hematinic nutrient'' assays in their armamentarium. Both nutrients are related to megaloblastic (macrocytic) anemia, and are therefore relevant to the diagnosis of this and related hematological abnormalities. The importance of subclinical folate deficiency, and of folate status in general, has become an important public health issue, because of the discovery that it is linked to the risk of neural tube defects (spina bifida, anencephaly) during very early pregnancy, and that it may be linked to vascular disease risk, via its effect on circulating homocysteine concentrations.

Both serum (or plasma) and red cell folate concentrations can give status information. The serum (plasma) assay is the more widely used and is simpler to perform, but it is also more affected by day-to-day fluctuations. The concentration in the red cells, which is much higher than that in plasma, is fixed at the time of production of the cells in the bone marrow and is therefore an integrated average index, representing a four-month period. However, it needs to be measured in a hemolyzed whole blood sample (the conjugate enzyme in the plasma being needed to release the monoglutamate form from the intracellular polyglutamate complex); it requires a hematocrit measurement and the sample needs to be stored with a reducing agent such as ascorbic acid. Storage conditions for the samples require careful attention.[255]

Traditionally, folate has been measured by a microbiological (growth) assay, using *L. casei*. The older rather cumbersome nephelometric assays using test tubes have now been modified to make use of the technology of ELISA plates and their automated readers.[256–258] With the discovery of a specific folate-binding protein in milk, alternative assays have been developed on the competitive protein-binding principle and marketed as a range of commercial kit assays, which are widely used by laboratories performing routine clinical or population survey work.[259–264] The problems of interlaboratory harmonization of these and other routine assays have not yet been fully solved[261–263] and there is a need for a ''gold standard'' assay, perhaps based on MS.[265,266] However, the existence of EQAS for folate and B_{12} in blood samples gives some degree of QC for these assays, even though the different versions of the assay do not give identical results. Contact details for these QA schemes are: (in the UK) Dr M.J. Lewis, National EQAS (UK), tel: +44 161 720 2483; fax +44 161 720 2886; (in the USA) College of American Pathologists Survey (Illinois), tel: +1 847 832 7000; fax: +1 847 446 8807.

Blood and tissue folate concentrations and, in particular, the study of the many different forms of folate that occur in tissues, require efficient separation and sensitive detection techniques, such as those of HPLC. A range of alternatives is available[267–274] and research in this field is intense. Although urine is not generally a useful source of information about intact folate, folate degradation products[275] and in particular their use for stable isotope folate labeling (turnover) studies.[276,277] are being studied in urine.

Folate in breast milk is not a useful source of information about maternal status.[39] There are several functional indices of folate status, of varying degrees of specificity and usefulness. These include plasma homocysteine (which is strongly dependent on folate status, but is also affected by other B vitamins), the excretion of formiminoglutamic acid (FIGLU) after a standard histidine dose, the deoxyuridine suppression test, which measures the efficiency of the de novo

pathway of thymidine synthesis, and the nuclear lobe count of circulating polymorphonuclear leukocytes. All of these are research, as distinct from routine clinical or epidemiological, tools.

4.10 Folate in Foods and Pharmaceuticals

The assay of folate in foods poses a major challenge because of the multiplicity of forms that are present, their limited stability and the complexities posed by variable bioavailability, especially of the polyglutamate forms. The tetrahydro forms of folate present in foods are easily oxidized, and some of the oxidized forms are biologically inactive. For this reason, it is advisable to include a reducing agent, usually ascorbic acid, in the extraction medium, and to minimize exposure to high temperatures or pro-oxidant conditions. Because of the great complexity of the folate polyglutamates that occur in foods and tissues, it is common practice to simplify the structure by an enzymatic deconjugation to the monoglutamate forms during, or immediately after, the initial extraction process.[1,278–282] Some procedures use thermal denaturation of proteins, others rely entirely on combination of enzymes, e.g. proteases to liberate protein-bound folate, α-amylase to degrade starch and folate conjugates from various sources to deconjugate the folate polyglutamates.

The three main approaches to the final assay and quantification steps have been microbiological growth assays, generally with *L. casei*, radioassays, using a competitive protein-binding principle and HPLC. Microbiological assay has the potential advantage that, with the correct choice of conditions, it should be possible to achieve equal potency for all biologically active forms of folate in the extracts. In practice this has proved difficult[1] and there remains a serious degree of uncertainty about the reliability of the *L. casei*-based assays for food folate analysis. Radioassay-based techniques also suffer from similar problems, because it is very difficult to achieve and maintain assay conditions in which all (and only) the biologically active forms of folate have equal affinity for the chosen folate binder. Although some laboratories have used this approach,[1,282] it appears to have serious drawbacks.

A considerable number of HPLC-based assays have been described[1,11,267,268,281–283] and there is a useful review.[284] The use of GC/MS is finding important applications in this area.[266,267] The problem of monitoring pharmaceuticals is much less difficult than that of food analysis, because the only form that is usually present is pteroylglutamic acid, which is stable and easily measured.

4.11 Vitamin B_{12} Indices in Serum, Plasma and Breast Milk

Not only are folate and vitamin B_{12} closely linked metabolically by their involvement in one-carbon transfer reactions, they are also similar with respect to the choices of status assays that are available: namely microbiological, competitive protein binding and HPLC. Because undiagnosed vitamin B_{12} deficiency due to pernicious anemia or related conditions can cause irreversible neurological damage, it is imperative that early diagnosis is made; hence the development of several commercial kit assays for clinical use, generally for use in hospital hematology laboratories. Initially, these were based on the semispecific ''R-binders'', which failed to distinguish between vitamin B_{12} and some structurally related, but biologically inactive corrinoids. These were replaced by intrinsic factor-based binding assays, which possess greater specificity and have proved to be more satisfactory.[285–293] The most recent development in this field is the use of fluorescent or chemiluminescent end-points, rather than radioisotope-labeled ligands, for protein binding assays for both folate and vitamin B_{12}.[264,290,292,293]

More detailed investigations of vitamin B_{12} status and its metabolism have required HPLC[294] or GC/MS techniques.[295,296] Because serum vitamin B_{12} (the usual clinical status assay) may fail to detect a deficiency in some individuals and some metabolic states, additional measurements based on the circulating vitamin B_{12}-binding proteins[297] or a functional assay based on serum or urinary concentrations of MMA[298] have been developed. Raised levels of MMA provide a specific indicator of tissue vitamin B_{12} deficiency, which is becoming of increased usefulness now that the initial problems of accurate measurement by GC/MS or CE, have been overcome. Other functional assays for vitamin B_{12} are also shared by folate, e.g. raised plasma homocysteine, the deoxyuridine suppression test and increased polymorphonuclear leukocyte lobe counts. The Schilling test specifically tests for impaired absorption of vitamin B_{12} using radioactive cobalt-labeled vitamin B_{12} in vivo. Breast milk vitamin B_{12} levels do vary with maternal status[39] and this is of potential concern for those nursing mothers whose dietary intake is extremely low (e.g. vegans) or those with B_{12} absorption defects.

4.12 Vitamin B_{12} in Foods and Pharmaceuticals

Vitamin B_{12} in foods is, like folate, relatively susceptible to degradation during extraction; it may be destroyed by strongly acidic or alkaline conditions and it is also susceptible to strong oxidizing or reducing agents. Extraction is designed to liberate protein-bound forms of the vitamin and to convert them to the more

stable forms, cyanocobalamin or sulfitocobalamin. This is usually achieved by heating in buffers under mildly acid conditions: metabisulfite can be used to achieve conversion to the sulfito form.

Microbiological assay is achieved by growth assays using *L. leichmannii* (now *L. delbruecki* (*lactis*)), or by the protozoan *Ochromonas malhamensis*.[1,7,9,285] Radioassay procedures, usually based on intrinsic factor as the specific protein binder and ^{57}Co-labeled cyanocobalamin as the tracer, have been used successfully. HPLC-based methods and GC/MS-based methods are potentially available[294,295,299] but have not yet been widely used. The form that is present in pharmaceuticals is cyanocobalamin, which is stable and fairly easily quantitated.[67,106]

4.13 Niacin Indices in Blood, Urine and Breast Milk

Whereas the measurement of niacin status was a priority during the outbreak(s) of pellagra in the first half of this century, especially in the southern states of the USA, it has had a lower profile in recent years and the assay procedures have therefore not progressed. The most widely used status assays are those based on urinary excretion of its degradation products, and whereas the early assays were relatively crude and based on the formation of a fluorescent derivative of N^1-methylnicotinamide alone, more recent versions have separated and quantitated both the N^1-methyl derivative and the pyridone breakdown products, thus achieving a more reliable picture.[300–304] It has been suggested that an N^1-methyl nicotinamide: pyridone ratio less than 1.0 in urine may indicate a deficiency of niacin.[16] Breast milk concentrations are moderately responsive to maternal status.[39] Studies[303,305–307] have suggested that the concentration of niacin-derived compounds formed from niacin in blood fractions may give useful information about niacin status, and although this has not yet been developed into a routine status assay, it appears to be of significant research importance.

4.14 Niacin in Foods and Pharmaceuticals

Studies of the niacin potency of foods need to take account of the fact that there are two main diet-derived sources of body niacin stores: preformed niacin (nicotinamide and its coenzymes and nicotinic acid) and the precursor amino acid, tryptophan. Tryptophan contents can be measured by amino acid analysis after alkaline hydrolysis (tryptophan is destroyed by acid hydrolysis) and it is usually assumed as an approximation that one sixtieth of the dietary tryptophan is available for niacin synthesis.[38,308]

Nicotinic acid and its amide are chemically stable, but some of the niacin in cereals may be locked up in the unavailable complex, trigonelline, which can only be liberated by alkali treatment (as occurs in the cooking of Mexican tortillas). Food extraction for analysis generally uses mineral acid extraction under autoclave conditions (e.g. 1 N sulfuric acid), although gentler conditions may be preferable for some foods. Final assay quantitation is either by microbiological assay using *L. plantarum* or *K. apiculata*, by colorimetry involving a reaction with cyanogen bromide and sulfanilic acid, or by HPLC with optical density detection.[1,7–9,11,99,309] GLC-based methods have also been used.[3,11] Niacin in pharmaceutical preparations is generally in the form of either nicotinamide or nicotinic acid, and both forms have been used in large daily doses for specific therapeutic purposes.

4.15 Biotin Indices in Blood, Urine and Breast Milk

Although biotin is an essential vitamin, overt biotin deficiency in humans is rare and is usually associated with inborn (genetic) errors of metabolism; therefore few analytical laboratories are called upon to measure biotin status. Biotin concentrations in plasma or urine can be measured by a microbiological assay,[16,310] and this was the traditional procedure for many years. Recently, specific protein-binding assays, based on the specific biotin-binder avidin or other specific binders, have been developed.[311–317] Recent studies of urinary excretion products[310,318–320] promise to provide more specific information. As with most vitamins, HPLC has proved useful for the separation and quantitation of biotin and its catabolites.[310,321–323] A status assay based on the in vitro reactivation of the biotin-requiring enzyme, lymphocyte propionyl CoA carboxylase, appears promising.[16,324] The concentrations of biotin in plasma and in red blood cells are similar,[16] and there is little information to suggest whether either one or the other is preferable as a source of status information. There is little information about the variability of biotin in breast milk.[39] Thus studies of biotin status indicators remain at an early stage of development.

4.16 Biotin in Foods and Pharmaceuticals

Biotin is relatively stable, but can be destroyed by extremes of pH and temperature and by powerful oxidizing agents. There are bound forms, notably biocytin, in foods and tissues and for foods of animal origin it is necessary to extract with high concentrations of strong mineral acids at high temperature (e.g. 6 N H_2SO_4 in an autoclave). Different tissues require different extraction conditions for maximum yield. Proteolysis, for example with papain, may be effective and preferable.

Microbiological growth assay of extracts is achieved using *L. plantarum* or by radioassay using the specific

biotin-binding protein, avidin, as the binder and ^{14}C or ^{3}H-biotin as the tracer.[1,7–9,316] Several new assay procedures, based on HPLC or specific binders have been described in a series of reports.[310–315] These will need to be assessed for their potential usefulness in food biotin determinations. Pharmaceutical preparations containing biotin can be assayed by electrophoresis or chromatography-based assays.[67,106]

4.17 Pantothenate Assays (Status, Foods, Pharmaceuticals)

Pantothenate deficiency is practically unknown in humans and is only likely to arise if pantothenate antagonists are ingested. Older studies of the pantothenic acid content of blood and tissues were based on microbiological assays,[325–327] but enzymatic, mass spectrometric and other approaches have now been reported.[327–329] There is little information about its variation in breast milk.[39] Measurements of the pantothenic acid contents of foods are needed, particularly in the context of the development of food tables, and both microbiological and chemical (e.g. specific binding) procedures have been developed for this purpose.[325–333]

4.18 Other Substances with Vitamin-like Properties

There are, of course, innumerable substances present in foods that may have beneficial and protective properties, even though specific deficiency syndromes for them have not been described except in special circumstances, such as inborn errors, or particular diseases, or at extremes of the age range. The analysis of dietary and blood carotenoids has already been referred to, in sections 3.1 and 3.2; some carotenoids are vitamin A precursors and most are antioxidants, although their relevance to human health remains poorly understood. Another, numerous group of dietary antioxidants is the polyphenols, including the bioflavonoids. HPLC-based assays are being developed to quantitate these, both in foods and in body fluids such as blood and urine. Several of the essential and quasi-essential components of our diet are lipidic: these include the essential fatty acids, plus the major phospholipid components choline and inositol and the important lipid-carrier L-carnitine. These can be assayed by the classical techniques of lipid analysis (GLC and so on) or by enzyme-based methods. Other quasi-essential dietary components, such as taurine, are amino acids and can be assayed by the classical procedures of amino acid analysis.

During most of the twentieth century, analytical technology has been unable to measure large numbers of diverse chemical substances in a single run, but it is likely that this limitation will diminish in the future, with the perfection of new and powerful recognition procedures, such as controlled fragmentation MS, combined with more efficient preliminary separation methods. It should, therefore, become possible to quantitate a much greater range of nutrients than has been possible hitherto and to start to investigate the long-term effects of subtle dietary modulation, focusing on lesser-known components, which may have been ignored in the past. These may prove even more significant for long-term health than the 13 substances which have already, largely for historical reasons, been given the status of vitamins.

5 PROBLEMS ENCOUNTERED IN INTERPRETING VITAMIN STATUS INDICES

For most vitamins, the amount present in the deeper tissues of the body and the amount obtained from the diet over a period of time bear some relationship to the concentrations that are found in serum or plasma, blood cells, ratio of urinary excretion and so on, so that one or more of these indicators can be used as status and/or intake indicators for each of the vitamins. However, there are many confounding factors that can disturb and complicate the relationship between the status indices and the intakes or body stores of the vitamins which they aim to reflect. First, the amounts in serum or plasma may be modulated by specific binding proteins: this is particularly true for vitamin A (retinol) in plasma, but to a lesser extent also for several other vitamins. Both vitamins E and K are concentrated in circulating lipoproteins or lipids and their serum or plasma levels are thus proportional to the lipid levels as well as to body stores. Another important factor that can affect serum or plasma concentrations of most nutrients is the acute phase reaction: some nutrients are transferred into the plasma by infections or inflammatory processes, others are transferred out, so that the ratio of circulating levels to body stores changes for the duration of the acute phase reaction. This is especially true for retinol, but it is also observed for several water-soluble vitamins. Some vitamin concentrations are also sensitive to variations in kidney function, which can alter the overall composition of the circulating fluids.

Vitamin concentrations within the cellular components of the blood should be less seriously affected by the disturbances listed above, and indeed it is true that cellular concentrations can be better long-term status indicators for some of the vitamins, such as folate, thiamin and riboflavin. However, there are no red cell status indicators available for the fat-soluble vitamins or for vitamin B_{12}. Although red cell indicators can be useful, they may

also be complicated, e.g. by anemia, or by certain genetic diseases. White cell-based indices should also be valuable, but the complexity and variability over time of the white cell fraction and the relative difficulty of isolating pure cell types, has made this approach difficult to develop.

Urinary concentrations of B-vitamins were favored as indicators in the early years of vitamin studies, but they have proven less attractive lately, because of the difficulty of collecting accurate 24-h (or other timed) urine samples, and because the rate of urinary excretion is not very sensitive to status variations, when status is relatively poor. This arises from the fact that the vitamins are normally only excreted into the urine when the amount in the blood rises above that of tissue requirements. Degradation products may be formed at a rate that is proportional both to intake and to status, and this has been used for studies on niacin and vitamin B_6.

6 SUMMARY

The vitamins are a diverse group of compounds, both chemically and analytically, because they comprise a range of biomolecules whose common properties reside solely in the fact that they are essential dietary components, which are needed in relatively small amounts to sustain life and good health. In addition, the major analytical challenges that they present are derived from the facts that (1) there is a need to quantitate them in a wide range of biological matrices, which include both foods and body fluids (for status indices); (2) the concentrations that are present are usually very low and the ratio to other components, which can be chemically very similar, is small; (3) they may be present in several or many chemically diverse but biologically interconvertible, forms; (4) some of them are labile to heat, extremes of pH, degradative enzymes and so on and (5) there is no single analytical approach that can quantitate all of them together within a biological matrix.

Vitamins have been divided broadly into fat- and water-soluble groups and each of these has been further subdivided, mainly on a functional basis. Historically, the B-group vitamins were measured by various microbiological assays and others were measured (if at all) by semispecific colorimetric assays. Nowadays, there are several more powerful techniques available, which include high-pressure liquid chromatography, with a range of detectors operating over a continuous range of selective modalities; RIA and ELISA-based techniques, which use specific protein-binding selectivities, enzyme reactivation techniques for certain B-vitamin status assays, and so on. The use of MS is gaining ground and can be combined with several other separation techniques, such as GLC, CE and so on. Measurement of vitamins in simple pharmaceutical mixtures (vitamin supplements etc.) is now reasonably straightforward.

The technical advances that these methodologies represent have greatly broadened the horizons of the vitamin analyst, and have permitted even some of the more difficult biological matrices to be addressed. However, the unsolved challenges of accurate vitamin analysis show little sign of receding, and there are very few, if any, laboratories worldwide that are currently able to measure all of the known vitamins in all known biological matrices. This remains a major challenge and a goal for the twenty-first century.

ABBREVIATIONS AND ACRONYMS

1 BACKGROUND

The technological directions of polymer-related industries at the beginning of the 21st century have been determined by the operative business and societal driving forces of the last decade of the 20th century. The resultant technological directions affect the product development cycle and shape characterization needs of the materials required. The role of polymer characterization, analysis and testing in the product development cycle is depicted in Figure 1. Product development is no longer a direct straight-line process from product design to product performance, bridged by polymer and product characterization, analysis and testing. The product development cycle is subject to the many constraints produced by the operative temporal business and societal driving forces. These constraints have grown during the last decade and include the following:

- product development costs
- raw material supply
- shorter product development and market introduction cycles
- energy conservation
- waste reduction
- governmental regulations
- safety, health, and environmental considerations
- product quality and consistency
- emphasis on customer needs and satisfaction
- public consumerism
- improved product–process–customer economics
- global competition
- improvement of shareholder value

As can be seen from Figure 1, the role of polymer characterization, analysis and testing is to facilitate product development in a highly constrained environment. For example, polymer product development has been strongly influenced by environmental considerations and government regulations. The ''Clean Air Act'' of 1990 is the driving force behind the development of coatings with significantly lower volatile organic content. Plastic packaging is being developed with built-in environmental degradability. For plastic containers, it has become very desirable to use plastics that can be readily recycled. The Environmental Protection Agency in the United States is increasingly taking a ''cradle to grave'' philosophy with regard to the minimization of organic volatiles generation, minimization of product waste generation and energy usage associated with the chemistries used in the development of a commercial product.

The global operative business and societal driving forces of the last decade have caused polymer-related industries to focus strongly on their core businesses and technological competencies. This focusing has produced a more targeted approach to product development and a significant change in corporate Research and Development culture. The product development process and its associated commercialization is no longer a sequential process from Research and Development to product introduction into the marketplace. The process has become highly nonlinear, nonsequential, and iterative, with many concurrent parallel paths. Often, product Research and Development, process scale-up, plant manufacturing, and quality assurance overlap, occur in parallel and feed back to each other in order to speed up product innovation and shorten the product development and market introduction cycle.

On a more fundamental level, very few new commodity building blocks (monomers) are expected to be developed because of economic, environmental and regulatory considerations. Increased strategic use of low levels of specialty building blocks, coupled with innovations in polymer reaction processes, is expected in order to add value to a polymer product within acceptable economic constraints. In general, structure–morphology–property considerations are becoming of paramount importance in the development of new products. Examples include high-performance engineering plastics and composites that require strategically designed polymers, polymer alloys, and blends; and strategically designed polymers for electronic and biopolymer applications. It is not a question of what building blocks are put together, but how to put them together to make unique polymer products. This approach requires polymer structure–morphology control down to the molecular level in order to enhance and improve properties in a cost-effective manner. A recent example of this approach is the development of new polyethylene materials with unique end-use properties through the application of

metallocene chemistry in conjunction with innovative reaction processes.

The polymer product development process depicted in Figure 2 shows that polymer characterization methodology is required in each step of the process to achieve two goals:

1. characterize the molecular architecture and physical properties produced by a particular polymerization method, mechanism and process;
2. characterize the polymer product resulting from product processing in order to relate surface and bulk properties and morphologies to application and end-use properties.

This process also is highly iterative, with changes sometimes being required in the polymer design or product processing, or both, during the product development and market introduction cycle.

Due to the ever-increasing complex nature of polymeric products, measurement of average properties is no longer adequate to characterize and elucidate the nature of such complex materials. A combination of polymer characterization and analysis methods, the use of ''hyphenated'' characterization techniques and/or multidimensional analytical approaches is required to provide a synergism of analytical and characterization information to establish structure, property and morphology relationships that can form a knowledge bridge between polymerization mechanism and end-use performance.

On the basis of an ever-expanding list of constraints to product development produced by the operative global business and societal driving forces, polymer characterization analysis and testing can be expected to take on an even greater role in the polymer product development cycle during the 21st century. This chapter on the application of polymer characterization and analysis methods to polymers and rubbers is a reflection of that expectation.

2 ABOUT THIS SECTION

This section is organized into four main areas of instrumental applications to polymers and rubbers: chromatography; spectroscopy; morphology; and thermal analysis/rheology. Each of these four instrumental application areas include the key polymer characterization methodologies and techniques that are expected to be highly relevant for analyzing complex polymer systems now and in the future. Each of these four main areas is by no means all-inclusive. However, reference will be made to other sections and articles in this encyclopedia that complement, overlap, reinforce and fill any voids or omissions in the four instrumental applications areas cited above.

2.1 Chromatography

There are seven articles in the chromatography part of this section, which include the following topics: (1) **Gas Chromatography in Analysis of Polymers and Rubbers**, (2) **Inverse Gas Chromatography in Analysis of Polymers**, (3) **Supercritical Fluid Chromatography of Polymers**, (4) **Size-exclusion Chromatography of Polymers**, (5) **Coupled Liquid Chromatographic Techniques in Molecular Characterization**, (6) **Field Flow Fractionation in Analysis of Polymers and Rubbers**, and (7) **Temperature Rising Elution Fractionation and Crystallization Analysis Fractionation**. This is a rather comprehensive section on the application of chromatography methods to the analysis of polymers and rubbers.

Contained in these articles are many examples of the use of hyphenated techniques, manifested by the use of multiple detectors with a given chromatographic method, as well as the use of multidimensional chromatographic methods. The reader also is referred to the *Coatings* section article on **Gas Chromatography in Coatings Analysis** for very closely allied polymer applications. In addition, the reader is referred to some of the theory and instrumentation sections and articles. In particular, the articles in the *Mass Spectrometry* section on **Gas Chromatography/Mass Spectrometry** and **Liquid Chromatography/Mass Spectrometry** are worth noting, as well as many of the articles in the *Liquid Chromatography* section, with particular emphasis on the articles on **Gradient Elution Chromatography** and **Supercritical Fluid Chromatography**. For the reader interested in the process applications of chromatographic methods and their potential applications to polymer reactors, the reader is referred to the section on *Process Instrumental Methods* and the articles on **Chromatography in Process Analysis**.

2.2 Spectroscopy

The spectroscopy part of this section consists of six articles on infrared spectroscopy and two articles on nuclear magnetic resonance spectroscopy. The infrared spectroscopy articles cover the following applications: (1) **Infrared Spectroscopy in Analysis of Polymers and Rubbers**, (2) **Infrared Spectroscopy in Analysis of Polymer Structure–Property Relationships**, (3) **Infrared Spectroscopy in Analysis of Polymer Crystallinity**, (4) **Infrared Spectroscopy in Analysis of Polymer Degradation**, (5) **Infrared Spectroscopy in Analysis of Plastics Recycling**, and (6) **Near-infrared Spectroscopy of Polymers and Rubbers**. The infrared spectroscopy articles cover a wide range of applications and do include examples of infrared spectroscopy-hyphenated techniques. Although this section does not contain an article on applications of Raman spectroscopy, the reader is referred to the *Coatings* section for an article called **Infrared and Raman Spectroscopy and Imaging in Coatings Analysis** and to **Ultraviolet and Visible Molecular Absorption and Fluorescence Data Analysis** in the section on *Electronic Absorption and Luminescence*. The reader also is referred to the theory and instrument section on infrared spectroscopy for details on instrumentation, infrared theory, data analysis and interpretation.

The articles on nuclear magnetic resonance in the section on *Polymers and Rubbers* cover the following applications: (1) **Nuclear Magnetic Resonance, Solid State in Analysis of Polymers and Rubbers**, and (2) **Nuclear Magnetic Resonance, Imaging of Polymers**. For applications involving the liquid state and polymers and coatings, the reader should see the article on **Nuclear Magnetic Resonance of Coating and Adhesive Systems** in the *Coatings* section. Also, the reader is referred to the theory and instrumentation section on nuclear magnetic resonance and electron spin resonance spectroscopy for details on instrumentation, nuclear magnetic resonance theory, data analysis and interpretation. The article on high-performance liquid chromatography with nuclear magnetic resonance in this section is of particular relevance for polymer-related applications.

Although there are no articles on mass spectrometry and fluorescence spectroscopy in the *Polymers and Rubbers* section, the reader is referred to the articles in the section on *Mass Spectrometry* and the section on *Electronic Absorption and Luminescence* with emphasis on the articles **Fluorescence Lifetime Measurements, Applications of**, and **Fluorescence Imaging Microscopy**. The reader also is referred to the article on **Atomic Spectroscopy in Coatings Analysis** in the *Coatings* section, for its obvious relevance to other polymer systems. For the reader interested in process applications involving spectroscopy, with potential applications to polymer reactors, the reader is referred to the section on *Process Instrumental Methods*, with specific attention to articles on **Near-infrared Spectroscopy in Process Analysis**, **Ultraviolet/Visible Spectroscopy in Process Analyses**, **Nuclear Magnetic Resonance and Magnetic Resonance Imaging for Process Analysis**, and **Raman Spectroscopy in Process Analysis**.

2.3 Morphology

The morphology part of this section consists of five chapters covering a range of applications with articles as follows: (1) **Atomic Force Microscopy in Analysis of Polymers**, (2) **Neutron Scattering in Analysis of Polymers and Rubbers**, (3) **X-ray Scattering in Analysis of Polymers**, (4) **Positron Annihilation Spectroscopy of Polymers and Rubbers**, and (5) **Pyrolysis Techniques in the Analysis of Polymers and Rubbers**. The reader is referred to the *Coatings* section for the articles on **Microscopy of Coatings** to evaluate how these techniques are used to assess the morphology of polymeric based coatings systems. Additionally, the theory and instrumentation section on X-ray photoelectron spectroscopy and Auger electron spectroscopy should be perused. The reader should also access the application section on surfaces, which has several articles on a range of microscopy techniques which have relevance for polymer surface morphology characterization. One area of morphology analysis not included in this section is the determination of the particle size of polymeric particles. There is an entire application section devoted to particle size analysis. The vast majority of

these articles are highly relevant to the measurement and characterization of polymeric particles.

2.4 Thermal Analysis/Rheology

The thermal analysis/rheology part of this section consists of five articles covering a range of applications that are highly complementary to one another in terms of information that can be generated on polymeric systems. These articles are as follows: (1) **Thermogravimetry of Polymers**, (2) **Dynamic Mechanical Analysis of Polymers and Rubbers**, (3) **Mechanical Properties of Polymers and Rubbers**, (4) **Dielectric Spectroscopy in Analysis of Polymers**, and (5) **Surface Energetics of Polymers and Rubbers, Characterization of**. The *Coatings* section is once again recommended to the reader for its polymer-related articles on **Mechanical Properties of Solid Coatings**, **Thermal Analysis of Coatings** and **Rheology in Coatings, Principles and Methods**. The reader is additionally referred to the theory and instrumentation section on thermal analysis for details on instrumentation, thermal analysis methods theory, data analysis and interpretation.

It is hoped that the articles in this section on applications of polymer characterization analysis and testing will provide the reader with an information and knowledge base relevant to the technical challenges of 21st century product analysis, problem solving and product development.

Atomic force microscopy (AFM), in which a sharp probe is employed for profiling surfaces with unique resolution, has developed into an invaluable multidisciplinary technique for advanced characterization of polymer materials. In its basic function, AFM provides high-resolution imaging of surface structures between the scales of a few nanometers to hundreds of micrometers. This capability is useful for quantitative analysis of surface microroughness of technological surfaces with high sensitivity and accuracy. The direct visualization of polymer structures, from single macromolecules to granular and lamellar nanostructures, to microphase separation and other morphologic patterns, makes AFM an important complementary tool for many of the techniques (light scattering, chromatography, optical and electron microscopy, X-ray diffraction analysis, etc.) employed in polymer analysis.

The advances in AFM of polymers are related to a better understanding of tip–sample force interactions and their use for examination of local sample properties. Different responses of the probing tip to surface locations with different mechanical and adhesive properties are the key for compositional imaging of heterogeneous polymer systems. Compositional mapping with AFM, which does not require any special sample treatment, substantially enhances its microscopic value. Visualization of individual components in block copolymers, polymer blends and semicrystalline materials can be performed with nanometer resolution. In addition to lateral compositional imaging, AFM probing of subsurface structures can be achieved for polymer samples with rubber-like top layers.

A further expansion of AFM applications is expected with the imaging of polymers at different temperatures. Monitoring of polymer structural changes at thermal phase transitions could help in the understanding of polymer melting, crystallization, recrystallization, glass transition and physical aging. In such applications, AFM will complement various thermal techniques.

The review describes the basics of AFM, practical aspects of its applications to polymers and presents a broad range of examples illustrating the main trends in AFM of polymer materials.

1 INTRODUCTION

Polymer macromolecules and polymer materials are characterized by a number of analytical methods that help us learn about their chemical structure, chain organization and mobility, polymer morphology and nanostructure, mechanical and thermal behavior and many

Encyclopedia of Analytical Chemistry

other properties. For example, diffraction and microscopy techniques are widely used for examination of structural hierarchy in polymer samples. Electron microscopy is a direct imaging tool that presents structures in real space. Diffraction techniques (X-ray, neutron, light, electron, etc.) are reciprocal space methods and a conversion of their data into a real space demands the use of structural models which might be subjective. Analysis of polymer thermal transitions and mechanical properties of polymers at different temperatures is performed using a number of calorimetric and mechanical methods. These methods and some others (NMR (nuclear magnetic resonance), vibrational spectroscopy, dielectric spectroscopy, optical birefringence and dichroism) indirectly provide valuable information about structural organization in polymer materials. Most of the methods mentioned are well established and routinely applied in research and industrial laboratories. Advantages of these analytical techniques as well as their shortcomings are known, and the latter limit our knowledge about the structure–property relationship in polymer materials.

The increasing importance of these materials in modern technology demands a more detailed characterization of polymers. Progress in polymer synthesis allows precise control of polymer chain structure and, therefore also allows fine tuning of architecture and properties of novel macromolecular structures and polymer materials. Studies of new catalysts, chain structure and its branching, and monitoring the self-assembly of polymer molecules into building blocks of supramolecular architecture, are only a few of the tasks to be accomplished. Also, the rapid development of nanotechnology and the important role of polymer materials in this field requires better understanding of polymer behavior and properties on micrometer and submicrometer scales. This knowledge is invaluable for the engineering of polymer nanomaterials, which will be top players in a variety of technological applications.

Many expectations for advanced polymer analysis are related to the use of AFM. This method was introduced in 1986[1] for high-resolution imaging of surfaces and was first applied to polymer samples in 1988.[2] The original idea was to reach atomic scale resolution in the profiling of surface structures and it was successfully demonstrated on a number of different materials. With the development of AFM applications, it appeared that it is a multidisciplinary technique with applications far beyond those of traditional microscopy. The sharp tip used in AFM, which has an apex tens of nanometers in diameter, can serve not only as a profilometry stylus but also as a tester for probing mechanical, adhesive and even more specific (magnetic, electric, optical, thermal, etc.) sample properties. One of the first important lessons learned from the AFM studies of polymer and biological samples was the need for low tip–sample forces to prevent damage to these soft materials. Since the introduction of an AFM tapping mode, which is most suitable for studies of soft materials, progress in its applications to polymer materials became substantial. Nowadays, this field is of interest to an increasing number of researchers in academic and industrial laboratories.

In this chapter, AFM applications to polymer materials will be overviewed. This goal is challenging because of the rapid developments in this field. Therefore, the main idea is to collect examples with longevity. A short introduction describes the history of scanning probe microscopy (SPM), the family of methods in which AFM is the most important player. Different AFM modes are illustrated by images of polymer samples. AFM applications to polymers will be described by numerous examples, which present direct visualization of polymer chains, nanometer-scale architecture of crystalline polymers, block copolymers, three-dimensional (3D) compositional maps of heterogeneous polymer systems, and polymer morphology together with its changes at thermal phase transitions. From the presented results, the reader will get an idea how AFM complements a large number of other analytical techniques and why for some polymer samples it can provide data which are not accessible by other means. Future expectations in AFM of polymers will be summarized at the end of the article.

2 SCANNING PROBE MICROSCOPY AND ITS DEVELOPMENT

2.1 Basic Principles of Scanning Probe Microscopy

The invention of scanning tunneling microscopy (STM) in 1982,[3] which allows a real-space visualization of surface structures with atomic resolution, has revolutionized microscopy. By placing a sharp metallic probe in the immediate vicinity of a conducting or semiconducting sample and applying an electric potential between these two electrodes, it is possible to detect a tunneling current and to use it for atomic-scale imaging, Figure 1(a). The latter has been achieved using a piezoceramic actuator, which pivots the probe over equicurrent profiles with subansgtrom precision.

A most remarkable example of the first STM applications is the image, which reveals a surface Si (7×7) reconstruction pattern, Figure 1(b). This image unambiguously demonstrated that atoms and atomic-scale defects could be visualized with the new technique and the observed packing motif confirmed one of the structural models of reconstruction on the Si surface. Initially, STM measurements were conducted in UHV (ultrahigh vacuum) but similar studies could also be performed under ambient conditions. Such possibilities have

Figure 1 (a) Set-up for STM, in which a metallic tip and a conducting sample are the two electrodes. Bias voltage is applied to the electrodes and the detected tunneling current is employed for surface imaging. (b) Atomic-scale STM image of a Si (7 × 7) surface, showing surface reconstruction. Scan size 10 nm × 10 nm. (STM image courtesy of Prof D. Sarid.)

attracted a large number of researchers to this field, especially after the first commercial scanning tunneling microscopes became available in 1988. It has been established that STM images actually present maps of partial electron density (electron density at the Fermi level) measured at the tip–sample separation.[4] Therefore, the rational interpretation of STM images demands a theoretical analysis,[5] and a direct correlation between the image and surface topographic structure might be misleading. Another difficulty of STM is related to the possibility of strong tip–sample force interactions, which are often not taken into account. Because the tip force could induce surface deformation, on some samples the STM images have been actually obtained on the deformed surfaces.[6] Despite these difficulties, STM is used for surface studies of conducting and semiconducting materials in a large number of research laboratories worldwide. STM studies of conducting polymers and carbon materials (carbon fibers, carbon black, etc.) have been performed to visualize surface topography, morphology and molecular-scale order.

The invention of AFM[1] was initiated by a natural desire to extend STM applications by making possible atomic-scale imaging of nonconducting materials. Instead of tunneling current, a more universal tip–sample force interaction was employed for surface imaging in AFM. A simple optical lever method[7] was successfully used for detection of small forces between the apex of a microfabricated tip, which is positioned at one end of a tiny cantilever, and a sample surface, Figure 2(a–c). In this method, the bending of the cantilever due to small tip–sample attractive and repulsive forces is magnified on a positional photodetector and a related signal is used for profiling the sample surface at a constant force level. Because the tip–sample force is proportional to the total electron density of the top surface atoms, AFM images more directly relate to surface topography than STM images. In contrast to STM applications, the first AFM studies were conducted under ambient conditions, and only later the possibility of AFM measurements in UHV was demonstrated. Imaging samples under liquid and in electrochemical environments are also possible with both techniques.

With developments in AFM applications the validity of this technique became evident. High-resolution profiling of surfaces has facilitated observations of atomic-scale surface steps, atomic and molecular lattices in a large number of inorganic and organic crystals.[5] Observations of single DNA molecules by AFM have promoted its application to different biological samples. It is also understood that the tip–sample force interactions in AFM should be considered while imaging soft materials (polymer and biological materials). Normal and lateral forces between the tip and the sample in contact AFM mode are of tens and hundreds of nanonewtons. Minimization of these forces is needed for nondestructive imaging of soft samples. This has been achieved in imaging under liquid.[8] With the introduction of a tapping mode,[9] in which lateral forces are practically eliminated, AFM studies of soft materials have further broadened.

The success of STM and AFM applications led to the development of a number of related SPM techniques, which are used for mapping surface magnetic, electric, thermal, and optical properties. These methods are also known as magnetic force microscopy (MFM),

Figure 2 (a) AFM set-up showing optical lever detection employed in AFM for detection of the cantilever deflection caused by tip–sample force interactions. (b) Scanning electron micrograph of etched Si probe, which consists of a 125-μm long cantilever and a sharp tip. (c) Apex of a Si tip.

Figure 3 Height image (a) and phase image (b) of a magnetic video tape obtained by MFM. The images were simultaneously recorded on 25 μm × 25 μm area. The height image shows surface topography and the frequency image reveals magnetic pattern.

electric force microscopy (EFM), scanning capacitance microscopy (SCM), scanning near-field optical microscopy (SNOM), and scanning thermal microscopy (SThM), and so on. A large number of applications have been developed with these techniques, however, a separation of the effects of these interactions and surface topography is a key problem in such applications. In MFM and EFM this problem is solved using a two-pass lift technique.[10] In this technique, the topography is measured in the first scan and magnetic or electric properties (using appropriate probes) are measured in the second scan over the same area. In the second scan, the

probe motion reproduces the measured surface profile (feedback is off) but with a vertical lift of 20–50 nm. Changes in frequency or phase of the oscillating ferromagnetic probe during the second scan reveal magnetic surface structures or surface variations in dielectric constant when a conducting probe is used. In this way, the effect of long distance electromagnetic forces is separated from those of mechanical tip–sample forces. The height and frequency images in Figure 3(a) and (b) give a practical example of how surface topography and magnetic pattern of video magnetic tape are visualized in MFM. The magnetic structures of the film are seen in the frequency image. This was an example showing that the measurement of the surface topography is a practical requirement of all scanning probe methods.

There is no doubt that AFM is the leading scanning probe technique. It allows examination of practically any kind of sample and is applied in increasing numbers of industries, while other SPM techniques are rarely used for industrial applications. So far, the semiconductor and data storage industries have benefited most of all. Automated AFM systems have been introduced for on-line control of roughness of Si wafers[11] and of pole tip recession in magnetic heads.[12] The characterization of polymer materials with AFM, which substantially complements more traditional microscopic and diffraction methods, is developing rapidly in research and development laboratories in the plastics, rubber, paint, biomaterials and paper industries.

2.2 Atomic Force Microscopy Instrumentation

A generic scheme of the atomic force microscope is shown in Figure 4. In this configuration, a piezoceramic scanner carries the probe over the sample. In the alternative configuration, Figure 2(a), the scanner moves the sample whereas the probe is fixed. Scanners include two cylinders, one assigned for vertical z-travel, another for lateral x, y motion. Because of nonlinearity, creep and other features inherent in polycrystalline piezoceramic materials, a linearization of the 3D motion of the scanner is performed with software correction. Different lateral and vertical standards are used for scanner calibration. After that, measurements of lateral dimensions can be performed with angstrom resolution and measurements of vertical dimensions can even attain subangstrom resolution. The maximal area, which is commonly covered by piezoceramic scanners, is ~150 μm on the side. Surface corrugations up to 5 μm in height can be profiled. Additional $X-Y$ stages are employed for positioning surface regions of interest under the probe.

Another key feature of AFM, which defines its unique capabilities for surface imaging, is the high force sensitivity of the optical lever detection. Surface imaging is realized with the electronic feedback system, which utilizes a signal from the four-segment optical positional detector. (Vertical segments are used for measurement of the cantilever deflections caused by normal tip–sample force. Horizontal segments are used for measurement of the cantilever torsion that is due to lateral tip–sample forces.) This signal, often called the error signal, is the difference between the actual value of the normal tip–sample force and its set-point value chosen by the operator. The differential signal is used to adjust the vertical probe–sample separation and keep the tip–sample force interaction constant during scanning. All these functions are realized using an electronic controller, which also communicates with an image acquisition computer. The variations in the cantilever–sample separation are converted into a height image with bright (dark) contrast assigned to high (low) surface locations.

Figure 4 Generic scheme of atomic force microscope with its main components.

Commercial scanning probe microscopes are manufactured by a number of companies in the USA, Japan, the United Kingdom and Russia. The most popular microscopes are the Nanoscope IIIa™, MultiMode™ and the Dimension™, which are shown in Figure 5. Both instruments can be equipped with tensile stages and heating accessories. The MultiMode™ is a compact microscope, which provides a whole spectrum of AFM modes and requires only minimal vibration and acoustic isolation. The limited size of the sample ($\leq$ 2 cm in diameter) is a limitation, which is overcome by the Dimension™ microscope. A close-up of the Dimension™ AFM head and a large sample (8 inch, or 20 cm, wafer) is shown in Figure 5(b). However, with the increase in instrument size more protection from acoustic and vibrational noise is necessary. This is accomplished by placing the microscope into a special enclosure, Figure 5(c). With the further use of AFM instruments in the semiconductor industry, the size of microscopes used

is increasing making possible examination of 300-mm wafers and their automatic on-line handling by robotic systems.

2.2.1 *Atomic Force Microscopy Probes*

Microscopic probes are invaluable components of all SPM instruments, and their quality substantially defines the practical value of these techniques. There are a large variety of AFM probes (the integrated cantilever and tip) that are commercially manufactured. Most of them are microfabricated from Si_3N_4 or Si. Various coatings are applied to these probes in order (1) to increase a reflectivity of their backside for improved detection of the bouncing laser beam, (2) to provide electric or ferromagnetic properties of the probe, (3) to implement a thermosensitive element at the apex, (4) to improve the tip apex wear. The cantilevers have triangular or rectangular shapes and their length varies in the 100–400-nm range. The tips are pyramidal or conical and several micrometers in height. The opening angle of these tips varies in a range between 30–90° and the apex radius can be as small as 5 nm. Specially prepared tips are required for profiling deep trenches (hundreds of nanometers wide and up to several micrometers deep). Triangular-shaped Si_3N_4 probes are most often applied to contact mode measurements and their spring constants are in the 0.1–0.01-N m^{-1} range. There are a larger variety of etched Si probes. Their rectangular-shaped cantilevers have stiffness in the broad range from 0.1 to 500 N m^{-1} and their resonant frequencies are in the range from 10 to 500 kHz. Soft probes are applied to contact mode measurements, whereas stiff probes are required for the tapping mode in order to retract the tip from a sample surface in each oscillation cycle. (Adhesion and capillary forces caused by liquid contamination layers attract the tip to the surface.) However, stiff probes might cause a surface deformation of polymer samples even in the tapping mode. Therefore,

(a)

(b)

(c)

Figure 5 (a) MultiMode™ atomic force microscope. (b) Close-up of the head and sample in the Dimension™ 3100 AFM microscope. (c) The Dimension™ 3100 AFM with an acoustic hood, electronic blocks, computer and monitors.

Figure 5 (*Continued*)

an optimal choice of the probe is needed for imaging of a particular polymer sample. The quality factor (Q) of the probe cantilever is another parameter to be considered in tapping mode applications. High-Q cantilevers are more sensitive to small force variations, whereas low-Q cantilevers are more suitable for precise height measurements in the tapping mode and also for fast scanning.

Besides the probes described, which are routinely used in AFM studies of polymers, several types of modified tip are known. For example, chemically modified probes can be prepared by coating the Si tips with gold and by chemisorption of thiolo-organics on gold surfaces. In these ways, tips with different chemical functionality and different physical and chemical properties can be prepared. Applying such probes one might expect detection of specific force interactions between the modified probes and surface locations with a different chemical nature. There are a number of results, which indicate such effects.[13] However, it is difficult to assign these results exclusively to the different chemical natures of these surface regions without considering differences in their mechanical and adhesive properties. The latter makes the interpretation of these effects much more complicated. Another problem of chemically modified Si or Si_3N_4 probes is the integrity of the coating at the apex during scanning that cannot be checked directly.

2.2.2 Sample Preparation

The attractive features of AFM applications to polymers and other materials include the ability to perform measurements under ambient conditions or under liquid with minimal sample preparation. Many polymer samples (thin layers, films, fibers) can be examined without any preparation. Spin-cast films and those prepared by dipping the substrate into polymer solutions are proper samples for AFM. In studies of the morphology and nanostructure of crystalline polymers, the flat sample surfaces can be prepared by melting a piece of polymer on flat substrate (mica graphite, Si wafer) and cooling. Afterwards a crystallized sample can be separated from the substrate, and the flat polymer surface which was in contact with the substrate, is most suitable for AFM studies. For polymer materials, which are prepared by extrusion, compression or injection molding, flat sample surfaces for AFM study can be made by ultramicrotome. In contrast to TEM (transmission electron microscopy), which requires preparation of ultrathin sections, polymer blocks with a flat surface are proper samples for AFM imaging. However, preparation of extremely smooth polymer surfaces is a not trivial procedure and it requires an optimal choice of knife material, and optimal temperature of the knife and the sample. AFM images reveal the imperfections of this sample preparation (scratches, chattering patterns, contamination traces, etc.) Freeze fracture of some polymer samples also can result in flat surface areas.

Another important advantage of AFM studies compared with electron microscopy is that there is no need for sample staining or coating with a metal layer. Differences in mechanical and adhesive properties of components in heterogeneous polymer systems, such as semicrystalline polymers, block copolymers, polymer blends and composites are employed for compositional AFM imaging. Compositional mapping of polymer blends and composites is successfully performed on flat polymer surfaces prepared using an ultramicrotome. However, caution should be exercised in observations of submicrometer structures and, particularly, features in the tens of nanometers size range because these features can be at least partially due to material fracture that occurs during cutting. This area has not been explored yet.

2.2.3 Imaging Artifacts

AFM, as well as other microscopic methods, is not free of various artifacts. Imperfections could be caused by the inexperience of the operator and related to choice of nonoptimal imaging parameters, including set-point values, scanning rate, and gains. Samples with varying roughness require adjustment of these parameters and tracking of the surface steps might be difficult. The ability to measure surface profiles while scanning in different directions (from $-X$ to $+X$ or from $+X$ to $-X$) helps to clarify these effects and to avoid them by optimizing scanning parameters. Also specific features of piezoceramic scanners such as creep, nonlinearity, and cross effects between different axes should be taken into consideration. These effects are enhanced when the sample is tilted with respect to the microscope plane.

Most obvious artifacts are clearly seen in the images. Among these are double tip effects, when additional ghost patterns appear together with the real ones. A bad tip causes these artifacts. This might happen because of a manufacturing defect, traces of sample material which have stuck to the tip, or because of tip damage. The tip apex can be damaged and flattened while scanning hard samples. A sharp Si probe becomes dull after scanning on a Si wafer at elevated tip forces. Then imaging of surface features, which are sharper than the dull probe, leads to the appearance of the tip profiles in the images. This is inverse imaging: the sample images the tip. Periodical linear patterns with a repeat distance of 1.5–2.5 μm, which are often seen in the images of flat samples such as mica are caused by optical interference, which occurs on the surfaces of the sample and the cantilever. Adjustment of

Figure 6 Main AFM operation (a) tapping, (b) contact modes. Note that in the tapping mode the cantilever base keeps the same deflection before and after engagement/scanning.

the position of the detecting laser beam on the cantilever minimizes this effect.

2.3 Atomic Force Microscopy Operational Modes

Several operation modes have been developed in AFM. The main imaging modes, contact mode and oscillatory or tapping mode differ in the way the tip interacts with the sample, Figure 6(a) and (b). In the contact mode, the tip scans a sample surface while being in permanent contact with that surface, Figure 6(a). The cantilever deflection is a measure of the force which is exercised by the sample. The tip–sample force is maintained constant during scanning by an electronic feedback. The correct choice of set-point force is an important decision to be made by the microscopist. If a polymer sample is heterogeneous with components which have different mechanical properties, then with an increase in tip-force the height image reflects a larger tip-induced surface deformation of the weaker component. This is demonstrated in the height images, which were obtained in the contact mode at different tip forces on the sample of multilayer polyethylene (PE), Figure 7(a–c). In this sample, layers of PE with different number of branches and different densities (0.92 g cm^{-3}, high-density material; 0.86 g cm^{-3}, ultralow-density) alternate with each other. Narrow strips of high-density polyethylene (HDPE) are elevated in height images recorded at high forces. This is a result of a strong tip-induced deformation of weak layers of ultralow-density polyethylene (ULDPE). In varying the tip force, one should check if such deformation is elastic or it might cause sample damage. Therefore, in applying contact AFM mode to soft materials, one should be aware of how accurately the height image presents a surface topography.

Figure 7 (a–c) Height images of multilayer PE obtained at different tip-forces (ca. 10, 30 and 80 nN) over the same area (60 μm × 15 μm). Below the height images are the cross-section profiles taken across the layers in the middle of the area shown in the images. (d) Height image of a larger area (60 μm × 30 μm) of the same sample obtained in the tapping mode. The surface region, which was previously scanned in contact mode, is in the center of the image.

In the tapping mode (Figure 6b), the tip comes into contact with the sample in every cycle of its oscillatory motion at (or near) the resonant frequency of the

cantilever. A drop in the cantilever amplitude when the sample is brought close to the probe is used to measure tip–sample forces. During scanning in the tapping mode, the probe comes only into intermittent contact with the sample surface. As a result, more soft samples can be examined in the tapping mode than in the contact mode. This is demonstrated by the height image (Figure 7d), which was obtained on a multilayer PE sample with the same probe that was used for contact mode images in Figure 7(a–c). In Figure 7(d), the area previously scanned and damaged in the contact mode is seen. Variations in the tip–sample force interactions in the tapping mode did not lead to damage of this sample. The advantages and disadvantages of both modes will be described below.

Probing the mechanical or adhesive sample properties with the AFM tip can be performed locally, at one surface point, without scanning. Force curves are recorded for this purpose. Force curves describe the probe deflection (contact mode) or variations in the cantilever amplitude (tapping mode) versus the vertical travel of the sample or the probe base towards and away from each other. Depending on the level of the tip force the surface deformation can be elastic or plastic. In the latter case, the tip makes an indent on the sample. Special probes with diamond tips, which have an apex of several tens of nanometers, are employed for such studies. After indenting, the surrounding area is scanned and the indent dimensions are determined from the AFM image obtained. Such a procedure is the basis of a nanoindentation technique that is widely used for measurements of local mechanical properties of different materials and coatings. Examples of local mechanical measurements of polymers will be discussed in section 3.3.

2.3.1 Contact Mode

In this mode, lateral scanning of the probe over the sample surface is initiated when the vertical bending of the cantilever, which is due to the repulsive tip–sample force, reaches the set-point level chosen by the operator. After this happens, lateral motion of the probe is initiated by the feedback control. Continuous motion of the probe from the $-X$ to $+X$ direction (fast direction) proceeds with small advances in the Y direction. Scanning rates are typically in the 0–3-Hz range and can be higher when scanning is performed on atomically flat surfaces or in submicrometer scan areas. Imaging is performed continuously and is monitored on a computer screen. Single images (typically 512×512 data arrays) are collected as data files. Various filtering and data analysis procedures can be applied to AFM images. A height image of banded spherulite of poly(vinylidene fluoride) (PVDF) is shown in Figure 8(a) which reflects the surface topography of the sample. Some details of topography are better seen in the deflection (or error signal) image, Figure 8(b), which resembles a map of derivatives of topography scan lines. For many practical applications, it is also useful to record the variations of the lateral tip–sample forces. To emphasize friction effects, imaging should be performed with the slow scanning direction perpendicular to the cantilever length. Lateral force images, which are collected simultaneously with the height images, reveal surface regions that have different mechanical and adhesive properties. This is demonstrated by the images of a rubber sample, shown in

Figure 8 Height (a) and deflection (b) images of banded spherulites of PVDF obtained in contact mode. The images were recorded simultaneously on surface area 50 μm × 50 μm.

Figure 9(a) and (b). Areas of different contrast, which are seen in the lateral force image, correspond to different components of this blend. Such differences might not be distinguishable in the height image.

The contact mode has proven itself capable of imaging atomic- and molecular-scale periodical lattices. Such images have been obtained for a large number of organic and inorganic crystals and also for polymers. Molecular-scale images of polymers were obtained on oriented samples of PE,[14] polytetrafluoroethylene (PTFE),[15] polypropylene[16] and polybutene-I.[17] The periodical patterns can be obtained in the height, deflection and lateral force images. The latter might provide a better contrast of the atomic-scale features. One such image is shown in Figure 10(a), where a periodical pattern of oriented PTFE is seen. Filtering of the image using a fast Fourier transform (FFT) procedure, Figure 10(b), gives a much clearer view of the chain arrangement. The interchain distance (0.56 nm) and the pitch (0.82 nm) along the polymer chains are consistent with X-ray data, which reveals a slightly twisted conformation of PTFE chains. Another AFM image in Figure 10(c) shows oriented chains of PE, which were revealed on the surface of highly oriented sample.

Figure 9 Height image (a) and lateral force image (b) of a blend of synthetic and natural rubber. The images were recorded simultaneously on surface area 12 μm × 12 μm.

Several AFM studies aimed to check molecular packing in polymer single crystals[18] and in samples prepared by epitaxial crystallization.[19] Images of normal and cyclic alkanes, which are short chain analogs of PE, reveal molecular-scale packing of their crystals in full agreement with the crystallographic data. Crystallization of long chain molecules proceeds via chain folding and single crystals of a number of polymers prepared from dilute solutions are actually thin lamellae with a well-defined crystallographic shape. An essential question, which has not yet been answered is, how perfect is the molecular arrangement of the lamellar surface? Different structural defects, such as chain ends, loops, and ''switchboard'' chain segments, could cause deterioration in the perfect adjacent-reentry arrangement expected for perfect crystals. A number of atomic-scale images, which show periodical lattices of single crystals of polymers (PE,[18] poly(ethylene oxide)[20]) are most likely to have been obtained with the probe penetrating through the topmost surface layer (or depressing it) and thus revealing chain packing inside these crystals. Similar data have been obtained with X-ray diffraction techniques. Imaging of polymer crystal surfaces at low tip–sample forces shows a grain nanostructure of lamellar surface,[21] which will be discussed in section 5.1.

It is worthwhile to consider critically the capabilities of atomic-scale images in contact AFM mode. When applied to thin and ultrathin layers (thickness above and below 100 nm, respectively), small and imperfect crystals, atomic-scale AFM images give structural information that might be difficult and even impossible to obtain by diffraction techniques. However, there is a definite limitation to such studies that is related to the fact that such imaging is not true atomic-scale imaging. It is most likely that several apex atoms stay in contact with the surface when the tip moves and the tip–force variations reflect the corresponding surface lattice. Therefore, in contact AFM mode observation of atomic-scale defects (e.g. vacancies) is not achieved. Later, the atomic-force defects were observed in UHV studies of several semiconductors (including Si (7 × 7) surface) when

Figure 10 (a) Lateral force image of PTFE chains in oriented layer deposited by rubbing. Image size 14 nm × 14 nm. (b) A part of the image in (a) after FFT filtering. Image size 5 nm × 5 nm. the oscillatory AFM mode was applied in so-called noncontact regime.[22] An UHV environment, which is essential for detection of ultrasmall tip–sample forces, is a serious obstacle to the broadening of such applications.

2.3.2 *Force Curves*

Following the first applications of contact AFM mode to polymers and, particularly, to biological objects it has become evident that tip–sample forces lead to surface modification and sample damage. Therefore, one should consider the tip–sample forces in more detail using force curves. The force curve describes the cantilever deflection as a function of the scanner travel, Figure 11(a). (In practice, force curve measurements are performed at frequencies in the 1–100-Hz range.) Upon approach of the sample, a probe initially experiences a small attractive force, which causes the cantilever to bend

downwards. Then the tip comes into contact with the sample and the cantilever deflects upward, reflecting repulsive tip–sample forces. When the sample is retracted from the probe, the tip is stuck to the sample by the capillary force. A layer of liquid contamination that presents on samples in air causes this capillary force. Therefore, a pull-off force is needed for tip disengagement and this causes hysteresis in the force curves. In some cases, the pull-off force might be used as a measure of adhesion between the probe and the surface.

The contributions of different forces acting on the probe and the samples are shown schematically in Figure 11(b). From this picture it is clear that under ambient conditions the tip force includes the capillary force of the liquid contamination layer. By adjusting the set-point deflection to the attractive force level near pull-off point, the imaging can be achieved with the lowest force possible for a given probe. However, this condition is unstable owing to possible tip disengagement and is not realized practically. Under these conditions, the capillary effect limits the minimal force for imaging in contact mode to ~5 nN. By placing the probe and the sample under liquid the capillary force could be avoided. This is

(a)

(b)

Figure 11 (a) When the sample approaches the tip (←, right-to-left) attractive force (point 1) slightly bends the probe down (Δ, cantilever deflection). Further sample travel will induce upward bending of the cantilever caused by repulsive forces (point 2). On reverse travel (→), the tip is stuck to the sample until the probe spring stiffness overcomes the adhesion/capillary forces (point 3). (b) Scheme of different forces acting on a probe.

(a)

(b)

(c)

Figure 12 (a) Force curves recorded in the contact mode in air and in liquid. (b) Force curve obtained on grafted poly (dimethylsiloxane). (Reproduced with permission from Aime and Gauthier.[23]) (c) Force curves obtained on glass and ULDPE samples. Strong deformation of the ULDPE sample ($z_1 - z_2$) at a cantilever deflection Δ_1 is evident from these curves.

seen from the comparison of force curves in Figure 12(a). In general, the tip forces under liquid can be one to two orders of magnitude less than in air. This finding had encouraged AFM applications to biological systems because measurements in the aqueous environment, which is more suitable for such samples, can be performed. However, imaging under liquid has its own limitations especially when knowledge of the material structure and

behavior under ambient conditions is required and when interaction with liquid is not desirable.

It has been found that surface material or even a single macromolecule, when stuck to the tip, is stretched during the disengagement. In such cases, the jumps in the force curve can be associated with a break in the stretched material or bonds in single macromolecules. This situation is described in Figure 12(b) which shows the force curve, which was measured on polydimethylsiloxane surface grafted to silica substrate.[23] First, a pull-out force is recorded when the tip become unstuck from the surface. On further withdrawal of the probe, the cantilever bends again because the polymer material stuck to the tip is stretched and this stretching force exceeds the cantilever's stiffness. The next disconnection happens when the ''bridge'' between the tip and the surface is broken. The events described happen in the tens of piconewtons force range. These highly sensitive force measurements allow mechanical properties of single macromolecules, including DNA to be evaluated, opening up another interesting research area.[24]

Analysis of force curves in the repulsive regions shows how mechanical properties of polymer samples can be examined. When the sample is rigid, such as a piece of Si wafer or glass, the cantilever bends upwards in a linear fashion defined by the cantilever's stiffness. For many polymer samples, their stiffness is close to that of the cantilever and the force curve could reflect the tip-induced surface deformation or a partial tip penetration into the sample. The slope of the force curve and the difference in the way the scanner travels to reach the same cantilever deflection define the tip-induced deformation of a soft sample, Figure 12(c). A more detailed analysis of the force curves in needed to clarify the effects of the sample viscoelasticity.[25]

The important conclusion from force curve studies is that they can be applied to local probing of mechanical and adhesive surface properties. An extension of this approach is realized in another mode known as *force volume*. In this mode, force curves are collected at a large number of points (64×64, 128×128 or 256×256) in the area of interest, and the data at any particular force level is presented as a map. In this way, surface maps of mechanical properties (taken as force data at strong repulsive force levels) or adhesive properties (taken as force data in the disengagement region) can be obtained.[26] A similar idea was implemented in the *pulsed force mode*, in which maps of mechanical and adhesive properties are collected at a broad range of frequencies.[27]

Mapping of the mechanical surface properties had also been achieved in *force modulation* (FM) mode. In FM, the probe, which scans the sample in the contact mode, is driven into a vertical oscillation with an additional piezo-actuator at its resonant frequency (5–8 kHz). This actuator is positioned at the fixed cantilever end. With the tip staying in contact with the sample, the cantilever with its base being the whole assembly periodically moves up and down (Figure 13a) and the cantilever amplitude in the deflection direction is measured by the laser signal reflected from the back of the cantilever. In other words, the force on the sample is modulated around the set-point level, which is chosen to scan in the contact mode. FM data (fast changing, amplitude in deflection) are collected simultaneously with topographic information (slow changing, averaged deflection). The amplitude response depends on the mechanical properties of the sample: on stiff surfaces the tip bounces from the sample and the amplitude is large, whereas on soft samples the tip deforms the sample or penetrates into it and the deflection amplitude is small. This is demonstrated by the images of the multilayer PE sample, Figure 13(b) and (c). The height image shows the sample topography with elevated and narrow strips of high-density PE layers. In the amplitude image, the darker contrast (larger amplitudes are coded by a darker contrast) of these narrow layers confirms their high modulus in comparison with that of the wide layers of ULDPE. Initially FM was introduced to differentiate between the responses of surface regions or components (e.g. carbon fibers in epoxy matrix) with a different elastic modulus, however, its capabilities are much broader though not well explored.

To extend the application of FM to viscoelastic materials, it was suggested that the phase shift between two periodical signals be measured, one for the driver and the other for the photodetector. In this approach, some analogy can be found between this approach and dynamic mechanical analysis (DMA), in which the phase lag between an oscillating load and the induced sample deformation are used for evaluation of the viscoelastic properties of polymer samples. Indeed, there is some correlation between the driving amplitude in FM and sample deformation in DMA, and also between the cantilever deflection in FM and the load applied to the sample in DMA. However, in AFM of polymers the sharp tip deforms a sample or penetrates into it. A theoretical description of the tip deformation of the viscoelastic media is rather complicated, and nonlinear tip–sample force interactions substantially limit transferability of AFM data to the macroscopic mechanical behavior of polymers determined in DMA experiments. An additional challenge is an appropriate description of the cantilever mechanics in FM. Also it is worthwhile to note that the combination of the contact and oscillatory modes employed in this mode restricts its applications to soft materials.

2.3.3 *Tapping Mode*

The need for small tip–sample force interactions has been recognized since the introduction of AFM. An

Figure 13 (a) Schematic view of FM mode. Height image (b) and amplitude image (c) obtained on multilayer PE in the FM mode. The images were obtained simultaneously on surface area 60 μm × 15 μm. The dark contrast in the amplitude image corresponds to larger deflection amplitudes.

initial suggestion was to make use of noncontact imaging in a pure attractive force mode.[28] Sensitive probes and oscillatory cantilever motion were needed for the detection of long range weak van der Waals interactions. Although several applications of noncontact AFM imaging have been developed (true atomic scale imaging in UHV, profiling of semiconductor structures with maximum resolution of few nm, etc.) progress in AFM of polymers is entirely determined by use of the tapping mode. In this mode, the tip intermittently contacts the sample for a short time thus avoiding development of the inelastic sample deformations.[9] In the tapping mode, lateral tip–sample forces are practically eliminated, allowing this mode to be applied to a broad range of soft materials. It appears that optimization of the tip–sample forces is the main issue for most AFM applications to polymers. In one respect, minimization of the tip force is required for a gentle profiling of polymer samples. Low-force imaging, which means a small tip–sample contact area, will also be beneficial for high-resolution imaging of samples such as polymers that are not well ordered. In another respect, tapping at elevated forces is extremely useful for the compositional imaging of heterogeneous polymer systems. Therefore, it is important to demonstrate how to optimize the tip–sample force interactions in the tapping mode.

In the tapping mode, reduction of the cantilever amplitude, which is determined at (or near) the resonant frequency of the cantilever, owing to tip–sample forces is used to obtain feedback during scanning. The amplitude of the free-oscillating cantilever, A_0, is typically in the 1–200-nm range. Whether to use a set-point amplitude A_{sp} or a set-point ratio, r_{sp} ($= A_{sp}/A_0$) is the choice of the operator. In contrast to the contact mode, in which the cantilever deflection is directly related to the tip force, the amplitude changes do not fully determine the tip–sample forces in this oscillatory mode. For imaging the surfaces of homogeneous materials, this does not cause problems, although they might occur in imaging of heterogeneous samples with surface corrugations of a few nanometers, see section 3.1.

The driving frequency in the tapping mode is typically chosen at the resonant frequency of the probe. For systematic AFM studies at different A_0 and A_{sp} it is important to find the resonant frequency of the probe in the immediate vicinity of the surface. (Far away from the surface, the resonant frequency of the cantilever will be higher because of reduced damping of the cantilever motion in a near-surface confined environment.[29]) A typical amplitude resonance curve of the AFM cantilever resembles that of a harmonic oscillator, Figure 14(a). The frequency dependence of the cantilever phase is also shown. The phase as well as the resonant frequency of the oscillator is a sensitive measure of the forces acting on the probe. Attractive forces acting on the AFM probe cause a negative shift of its resonant frequency; repulsive forces cause a positive shift. If the phase of the oscillation is measured at the initial resonance frequency, w_0 (as happens in tapping mode), the phase of the oscillation will be negative (with respect to its level at w_0) in the attractive force regime and positive in the repulsive force regime. The phase changes are instructive for clarification of the tip–sample force interactions in the tapping mode. The amplitude versus distance and phase versus distance curves (Figure 14b) show how amplitude and phase of the oscillating cantilever change when the separation between the sample and the cantilever's base is reduced. When an amplitude drop is small, a negative phase indicates that the overall tip–sample interactions are attractive. With a further amplitude drop, repulsive interactions become dominant as seen by the switch in phase from negative to positive. These interactions also depend on the magnitude

Figure 14 (a) Amplitude versus frequency and phase versus frequency relationships for harmonic oscillator with resonant frequency w_0. Attractive forces cause a low-frequency shift of these curves (- - - -), repulsive forces cause a high-frequency shift (– · – · –). (b) Amplitude versus travel and phase versus travel curves recorded in tapping mode on high-density PE. (c) Amplitude versus travel curves obtained on ULDPE and a Si wafer.

of the initial amplitude A_0. When A_0 is small (1–5 nm), phase changes are negative at all amplitudes. Under these conditions, tip–sample interactions are always attractive. At large amplitudes (above 60 nm), the phase changes are always positive owing to the dominant repulsive force interactions. These results are typically obtained on surfaces of PE samples.

Amplitude curves recorded on polymer samples deviate from the straight line which describes the amplitude drop when the sample is hard such as Si wafer. In the latter case, the amplitude drops linearly with the sample travel and vanishes totally when the sample surface coincides with the cantilever baseline, see also Figure 6(b). (On further vertical travel the cantilever bends up and this leads to the appearance of a deflection signal similar to that in the contact mode.) On the soft samples, owing to this tip-induced deformation or even penetration, the amplitude curve is very different from that on the hard sample. As an example, the amplitude curve which was obtained on ULDPE is shown in Figure 14(c). At each A_{sp} value, the difference between this curve and a straight line, which simulates the curve on the rigid sample, defines an amount of tip-induced sample deformation or of tip penetration. Several examples of imaging at different tip penetrations will be given in sections 5.1 and 5.2.

Although the force interactions in the tapping mode are described by the amplitude and phase curves, it is important to understand how A_0 and A_{sp} influence the AFM images of polymer samples. This question was discussed earlier, and it was found that with an increase of A_0 and a decrease of A_{sp}, tip forces become stronger. An evaluation of the tip–sample forces in the tapping mode is not straightforward because the force changes in each cycle. Therefore, it will be instructive to judge these interactions by considering force-induced sample changes. The model system, a binary blend of HDPE and ULDPE prepared in a melt, can be used as a convenient model sample for examining tip–force effects. The elastic moduli of the components are quite different, therefore it becomes possible to observe tip–force-induced height changes. Height and phase images of the different sample imaging conditions are collected in Figure 15(a). The topography of the sample shows a number of bumps, which appear to be high-density PE regions. With the increase in A_0 and decrease in A_{sp}, these structures become more pronounced related to the strong deformation in their surroundings, which is ULDPE. The contrast in the phase images reveals different components of this blend, however, an assignment of ''dark'' or ''bright'' regions to individual components is rather ambiguous.

To understand better the relationship between the phase image contrast and surface regions with different densities it is instructive to analyze cross-section height and phase profiles taken along the same surface regions, Figure 15(b). These data were obtained at $A_0 = 100$ nm

Figure 15 (a) Height and phase images of the HDPE/ULDPE blend, prepared in a melt. The images were obtained on surface area 3 μm × 3 μm The images at the top were obtained at $A_0 = 20$ nm and $r_{sp} = 0.7$; the images in the middle were obtained at $A_0 = 100$ nm, $r_{sp} = 0.5$, and the images at the bottom were obtained at $A_0 = 80$ nm and $r_{sp} = 0.15$. (b) Set of height and phase cross-sections along the 3-μm long regions of the HDPE/ULDPE blend. Measurements were performed at $A_0 = 100$ nm and different r_{sp}.

and r_{sp} in the 0.95–0.1 range. When r_{sp} is close to 1, the profile in the height image presents a true surface topography. Note that the phase curve is located almost at the zero level indicating an absence of noticeable tip–sample force interactions. This imaging regime is known as *light tapping*.[30] With the decrease in r_{sp}, the ''bumps'' become higher owing to stronger tip deformation of the soft regions. This deformation can be described as elastic because the height and phase changes at r_{sp} in the 1–0.1 range are reversible. The phase changes also become evident with high-density spots exhibiting more positive phase changes. The maximum phase difference of the stiff and soft regions is observed at $r_{sp} = 0.4$–0.5, and it gradually disappears at small r_{sp}. Under the same conditions, the effective height of the ''bumps'' continues to increase.

The height changes in the low-density and high-density regions versus r_{sp}, which were recorded at different A_0 and A_{sp}, are summarized in Figure 16(a). The height versus r_{sp} curves show that at small A_0 the decrease of r_{sp} from 1 to 0.4 does not lead to any substantial height changes, and only at lower r_{sp} does the tip-induced surface deformation cause an increase of the height of the high-density regions. With an increase of A_0, the height versus r_{sp} dependence becomes different. At high r_{sp}, the height has already increased and it exhibits a local maximum at $r_{sp} = 0.5$. With a further decrease in r_{sp}, the height slightly decreases, and at small r_{sp} it increases again. The similarity in the height changes for all amplitudes at very small r_{sp} (0.2–0.1) is most likely to be due to a loss of the ''tapping'' character of the probe. Under these conditions the tip spends most of the time in contact with the sample (quasicontact) and the tip-induced surface deformation is determined mostly by the cantilever spring constant and it does not depend on A_0.

The phase changes which were measured on the regions of different density at $A_0 = 100$ nm and $A_0 = 20$ nm are shown in Figure 16(b) and (c). In imaging with large A_0, the positive difference between the phases in the high-density and low-density regions is observed for almost all r_{sp}. The maximal phase contrast between components is at $r_{sp} = 0.4$–0.5, i.e. under the same conditions as when the difference in the mechanical properties is visualized in the height images. This correlation allows the suggestion to be made that with *hard tapping*, the phase contrast is governed mainly by the different mechanical properties of the sample regions or components. More complicated phase behavior with contrast reversal is seen for imaging at smaller amplitudes when a more complex interplay between capillary effects, adhesive interactions and mechanical properties defines the phase changes. Therefore, imaging with larger A_0 and $r_{sp} \sim 0.4$ (''*hard tapping*'') is of more practical importance because it facilitates the assignment of phase contrast to the components with different mechanical properties. In the case of different PE, acrylic blends and elastomeric systems, stiffer components can be identified by their more positive (brighter) phase contrast in the phase images obtained by *hard tapping*. The great sensitivity of the phase changes to the sample heterogeneity is a key feature of the tapping mode in its application to polymers. In many heterogeneous polymer samples the differences in the elastic moduli of the components are not so drastic as in the case of the PE blends discussed above.

Figure 16 (a) ''Height'' difference between regions of HDPE and ULDPE obtained at different A_0 and different r_{sp}. Unlinked empty diamonds correspond to $A_0 = 5$ nm; cross-hatched diamonds to $A_0 = 20$ nm; linked empty diamonds to $A_0 = 40$ nm; black diamonds to $A_0 = 80$ nm. (b) and (c) Phase differences between the regions of HDPE (open points) and ULDPE (filled points) obtained at different $r_{sp} = A_{sp}/A_0$. $A_0 = 20$ nm (c) and $A_0 = 100$ nm (b).

Therefore, even with *hard tapping*, the height variations in these materials are hardly distinguishable, whereas the phase contrast provides component recognition.

Phase imaging has become a useful addition to the tapping mode because the phase contrast allows visualization of different components of heterogeneous polymers. However, assignment of phase contrast is not straightforward and a number of theoretical approaches are applied to address this problem. From the experimental data, phase contrast can be assigned to variations in mechanical or adhesive properties of components or surface regions. In a more general case, phase changes in the tapping mode strongly depend on energy dissipation.[31] Correlation between the energy dissipation at the tip–sample junction and the sample position is shown in Figure 17(a–c) together with the amplitude and the phase curves. All these dependencies were obtained on the surface of Si wafer.

In the absence of dissipation, when the amplitude of the oscillating cantilever is not restricted by the set-point value, the relation between the phase and amplitude of the cantilever is defined by symmetric branches $\phi = \pm \arcsin(A/A_0)$. These branches are relevant to the operation either in the attractive force regime (negative phase) or in the repulsive force regime (positive phase). In such cases (for example in the lift scan in MFM or EFM), phase and amplitude are strictly bound. Because the amplitude is kept constant (feedback is off) in the tapping mode, this relationship breaks down and phase changes are caused by the energy dissipation in the tip–sample junction, Figure 17(a–c). The experimental phase curves lie within the ''arcsin'' branches and the transition from the attractive to repulsive force regions means a ''jump'' from the lower to the upper branch, Figure 17(d). Although this transition is not specific in terms of energy dissipation, it can complicate the interpretation of phase contrast, which is defined with respect to the 90-degree level. (For simplicity this level so far has been defined as 0°). Figure 17(d) also demonstrates the correspondence between experimental data and the calculations, which were performed considering the interacting cantilever as a weak nonlinear system.[32] A number of phase curves derived from the calculations, which accommodate elastic deformation, adhesion and dissipation terms (K, w and α_s, respectively), all fall within the ''arcsin'' branches. It was also indicated that at low r_{sp} the tapping mode probe becomes a strong nonlinear vibration system. Therefore despite the fact that tapping mode results obtained on some elastomeric systems can be treated in terms of a simple harmonic oscillator[33] this approach is not general. To summarize, progress in the theoretical description of the tapping mode has brought a better understanding of the probe behavior and emphasized the energy dissipation in the tip–sample junction as a primary event. However, separation of the contributions of the different interactions to the phase behavior remains a challenging problem in AFM analysis of multicomponent polymer samples.

Figure 17 (a) Amplitude, (b) phase and (c) dissipation of the cantilever as a function of sample travel. (Reproduced from Cleveland et al.[31]) (d) Phase versus A_{sp} under different interaction conditions. (Reproduced from Wang.[32]) F_+ and F_- correspond to repulsive dominated and attractive dominated branches, respectively. Mechanical and adhesive interactions ($K = 2$ GPa and $w = 0.4\,\mathrm{N\,m^{-1}}$) are the same for all curves except F_+ and F_-.

$$P_{tip} = \frac{kA^2 w_0}{2Q}\ \frac{A_0}{A}\sin(\varphi) - 1$$

where P_{tip} is power dissipated at the tip–sample junction. A is the set-point amplitude, A_0 is the amplitude of a free-oscillating cantilever and Q is the quality factor.

3 EXAMINATION OF SURFACE TOPOGRAPHY AND LOCAL PROPERTIES

A number of practical examples, which illustrate the unique capabilities of AFM in studies of polymers, are presented in sections 3–5. Many examples show how AFM complements other characterization techniques. Most results were obtained in the tapping mode, recording height and phase images. Height images reveal surface topography and characteristic morphologic features of crystalline polymers, of oriented samples and of microphase separation. In studies of homogeneous samples, phase contrast often helps to visualize fine features of polymer morphology and nanostructure. Phase imaging is invaluable for compositional mapping of heterogeneous polymer systems. In tapping mode imaging, the driving frequency is chosen at the resonant frequency of the cantilever in the immediate vicinity of the sample surface. This does not exclude the possibility that other frequencies can also be used for imaging. For recording height images, which most correctly present true surface topography, small A_0 and high A_{sp} are applied. Such conditions are most favorable for high-resolution imaging owing to the minimal tip–sample contact area. Imaging at an A_{sp} of 0.5–0.4 A_0 and large A_0 (*hard tapping*) was used for compositional mapping of heterogeneous polymer samples. These conditions should be considered only as a preliminary idea of those needed for imaging of polymer samples. In practice, one should use a whole spectrum of parameters to optimize AFM imaging towards the problem being studied.

3.1 Surface Topography and Roughness

Initially, high-resolution surface profilometry was a primary goal of AFM, and this feature is useful in imaging research and industrial polymer samples. Surface corrugations from several nanometers to several microns can be examined quantitatively. Two examples of surface roughness measurements with AFM are presented in Figure 18(a) and (b). Surface corrugations in the height image of poly(methyl methacrylate) (PMMA) photoresist, which was deposited on a Si wafer by spin coating, (Figure 18a) are described by the following roughness parameters: $R_{ms}(R_q) = 0.394$ nm and $R_a = 0.314$ nm. After chemical mechanical polishing bare

Figure 18 AFM height images of a photoresist (PMMA) layer on Si wafer (a) and polycrystalline Si sample (b). Image size is $2\,\mu m \times 2\,\mu m$ in (a) and $3\,\mu m \times 3\,\mu m$ in (b).

Si wafers are characterized by smaller roughness with R_{ms} (R_q) and R_a below 0.2 nm. AFM evaluation of the surface roughness of Si wafers is employed for quality control in the semiconductor industry.[11] Considerable roughness is desirable for polycrystalline Si surfaces, which are used in the manufacture of stack capacitors, and the AFM image of the polycrystalline surface in Figure 18(b) reveals its surface roughness with $R_{ms}(R_q) = 8.113\,nm$; $R_a = 6.553\,nm$.[34] Imaging with *light tapping* facilitates accurate roughness measurements because it provides not only a small contact area but also prevents wear of the probe apex.

The technological surfaces described above are relatively flat, and they do not require special probes, in contrast to those applied to more complicated measurements of surface structures with critical dimensions, such as steps and trenches. In order to measure angles of steep surface steps or roughness at the bottom of narrow trenches (a few microns in depth and hundreds of nanometers in width) AFM probes with special geometry are needed.

The surfaces of most polymer samples are relatively flat and can be examined with conventional Si probes. Measurements of surface roughness with AFM are useful for studies of paint and polymer coatings. The height image of acrylic paint (Figure 19a) shows a surface with averaged corrugations $R_{ms}(R_q) = 36.771\,nm$ and $R_a = 28.057\,nm$. Graphs, which show a linear correlation of AFM data with gloss measurements at two different angles of incidence, are presented in Figure 19(b).

Figure 19 (a) Height image of one of 18 PVC paints. Contrast is in the 0–500-nm range. Image size is $100\,\mu m \times 100\,\mu m$. Statistics for the image and the box, which confines a part of the surface area (black lines) are shown beside the image. (b) The relationship between surface roughness (R_a) and gloss, measured at 60 (filled dots) and 20 (open dots) degrees, for 13 different paints.

Quantitative estimates of the surface roughness of various coatings provided by AFM are useful for correlation with their optical properties and appearance. AFM evaluation of surface roughness is important for samples of thin and transparent coatings on substrates which are difficult to examine by optical means.

More extensive AFM studies were performed on model systems of the paints such as acrylic latexes.[35,36] AFM images reveal the morphology of latex surfaces and their packing motifs (Figure 20a). At higher magnification, the submicron structure of individual latex particles can be examined. Height and phase images of the polystyrene (PS) latex layer show only small surface corrugations on individual particles, which are noticeable only in the phase image, Figure 20(b). A ''berry-like'' particle structure of PMMA latex is seen in the AFM images in Figure 20(c). Again, these structural features are more pronounced in the phase image.

Figure 20 (a) Height image of PS latex layer showing close-packed layer morphology. Scan size 20 μm × 20 μm. (b) High-resolution images of PS latex. Scan size 1 μm × 1 μm. (c) High-resolution images of PMMA latex. Scan size 1.5 μm × 1.5 μm.

It is worth noting that because of the perfect shape of latex particles, which can be prepared in different sizes, they are suitable for testing the quality of AFM probes. The surface area difference (a difference between surface area of corrugated features and surface area of the flat plane), which is calculated from height images of a single latex layer, would be greater if the tip correctly tracks surface locations between neighboring particles. In this way probes that are most appropriate for reliable measurement of surface corrugations can be chosen. The latter are often employed for monitoring film formation in polymer latex systems.

Many polymer surfaces show morphological features with various degrees of order and regularity. The surface topography of liquid crystalline polymers reflects their regular architecture, which correlates with their optical behavior. An optical micrograph and AFM images of a cholesteric liquid crystalline copolymer, which both reveal a focal-conical texture, are presented in Figure 21(a) and (b).[37] Thermal annealing of this copolymer at 153 °C induces its transition from the focal-conical to the fingerprint texture, Figure 21(c). Selective optical reflectivity of the cholesteric copolymer is directly related to its texture and its spectrum correlates with the width of rings of the fingerprint texture seen in the AFM images.

Another example of a polymer sample with well-defined morphology is an industrial film of microporous isotactic polypropylene (iPP) (Celgard™ 2400). The morphology of this film, which was examined with SEM and AFM (Figure 22a–c), is characterized by alternating fibrillar and lamellar regions.[38] The lamellar regions are slightly elevated compared to the fibrils. The latter are not closely packed and, therefore, precise profiling of these fibrils with an AFM tip might be difficult owing to the tip convolution. These structural features (fibrils and holes between neighboring fibrils) are more correctly reproduced in the SEM micrograph (Figure 22a) than in the AFM height image (Figure 22b). However, visualization of the polymer nanostructure is superior with AFM, which is evident from the phase image in Figure 22(b). Therefore AFM is useful for detection of minor structural changes in polymers caused by various technological treatments. Comparison of the images of the Celgard™ 2400 membrane prior to and

Figure 21 (a) Optical micrograph of focal-conical texture of cholesteric liquid crystalline polymer. (b) and (c) AFM images revealing focal-conical and fingerprint textures of cholesteric liquid crystalline copolymer, respectively. Scan size 10 μm × 10 μm.

after argon plasma treatment (Figure 23a and b) shows drastic changes in its nanostructure, whereas overall morphological features remain the same. These changes are caused by condensation of small water droplets from air. It happens because the plasma treatment makes the iPP surface hydrophilic.

Visualization of the morphology and nanostructure of ultrathin polymer films is a capability offered only by AFM. The height image of poly(ε-caprolactone) (ε-PCL) grafted to a Si surface (Figure 24) demonstrates this capability. The image shows the crystalline morphology of a 10-nm thick ε-PCL film, which was prepared by spin casting.[39] Numerous fibrils are spread over the surface along with flat lying lamellar sheets. These parts of growing two-dimensional (2D)-spherulites are the main structural features of the crystalline layer. A deficit of material prevented complete coverage of the substrate surface, and the cross-section profile taken along the *x*-axis, which is shown above the image, can be used for thickness measurements. The same measurements of thin polymer or organic layers, which cover the substrate completely, can be facilitated by scratching away part of

Figure 22 (a) Scanning electron microscopy micrograph of microporous iPP film (Celgard™ 2400). (b) and (c) AFM images of the same film. Scan size 5 μm × 5 μm in (b) and 2 μm × 2 μm in (c).

the layer with an AFM tip in high-force imaging (contact mode will be better for this purpose).[40]

Thin films and layers of block copolymers are routinely examined by AFM. The height and phase images of a thin layer of PS-*b*-PMMA, which was transferred on to a mica substrate from a water subphase in the Langmuir–Blodgett trough, are shown in Figure 25(a–c).[41] Hydrophilic PMMA blocks are spread as a first layer, whereas hydrophobic PS blocks aggregate on top. Imaging in *light tapping* allows evaluation of the thickness of the PS blocks (25–30 nm) and visualization of fine details (5–8 nm) of these blocks, Figure 25(c). The phase separation in the vertical dimension, which exists in this block copolymer film, defines a different response of the PS and PMMA blocks to the AFM probe with *hard tapping*. With the increase of the tip force, PS blocks are deformed more substantially than PMMA blocks. This is seen from the reduced brightness of PS blocks in the height image and dark appearance of these blocks in the phase image (Figure 25b). In other words, PS blocks, which are further from the substrate than PMMA blocks, are compressed by the probe to a larger extent than PMMA blocks, which lie directly on the substrate. When the tip force was reduced again,

the images became the same as in Figure 25(a), which is an indication of the reversible character of the sample deformation.

3.2 Surface Topography in Heterogeneous Polymer Samples

In studies of the topography of thin films which do not cover the substrate completely, and surfaces of other heterogeneous polymer samples, one should be aware of the possible drawbacks of AFM imaging when the topographic differences are a few nanometers in height. These polymer samples, which in addition are soft, are nontrivial for AFM topographic studies. Application of the contact mode for this purpose could induce sample deformation, which will be different for different sample components. Therefore, the height image will not reflect the surface topography correctly. There is also a problem in tapping mode applications. This problem is caused by the shift of the resonant frequency of the cantilever that leads to a drop in the cantilever amplitude measured at the resonant frequency of the free-oscillating cantilever. Therefore, when surface regions exhibit different properties (e.g. adhesive, mechanical, etc.), which cause different frequency shifts, then corresponding surface areas could appear in the height images with a fake topographic contrast, which is in range of the few nanometers. This effect, which is intrinsic to the tapping mode with amplitude feedback, should be considered while studying surface corrugations of a few nanometers in scale.

Figure 23 (a) AFM images of microporous polypropylene film Celgard™ 2400. (b) AFM images of the same area as in (a) after Ar+ plasma treatment. Scan size 3 μm × 3 μm in all images.

Figure 24 Height image of a 10-nm thick film of ε-PCL grafted to a Si surface. Scan size 4 μm × 4 μm. The cross-section profile shown above the image was taken along the (→ ←) direction.

Height images of an ultrathin film of PS-*b*-PMMA block copolymer, which was prepared by spin-coating on Si substrate, will be discussed to illustrate these effects. The way to minimize these effects will also be shown. Typically, the height images of this film show small height variations of PS and PMMA blocks, which reveal microphase separation in such polymers.[42] The image of the PS-*b*-PMMA film in Figure 26(a) reveals the microphase separation by showing a pattern similar to that usually determined by TEM. Although in TEM micrographs the different contrast in the PS and PMMA blocks is explained by thinning of the PMMA regions caused by electron beam-induced degradation, the reason for the contrast in the AFM images is not well understood. The fact that in Figure 26(a) and (b) a contrast is seen both in the height and phase images indicates that the probe interacts differently with PMMA and PS blocks. This causes variation of the ''heights'' of the corresponding regions, with some being higher than others in the height image recorded with *light tapping*, and lower in the

Figure 25 AFM images of a single layer of block copolymer PS-*b*-PMMA recorded in *light tapping* (a) and in *hard tapping* (b). Scan size 1 μm × 0.5 μm. (c) PS blocks shown at high magnification. Scan size 200 nm × 200 nm.

height image recorded with *hard tapping*. True sample topography for this sample was recorded by imaging with a softer Si probe, Figure 26(c). The height image recorded with *light tapping* (Figure 26c, top) reveals no differences in the height of PS and PMMA blocks. The fact that the corresponding phase image is almost featureless indicates that the tip interactions with PS and PMMA blocks are negligible. With *hard tapping*, these interactions become different causing a microphase contrast in the height and phase images (Figure 26c, bottom). This example shows that imaging in different operation regimes using probes of different stiffness is a way towards rational interpretation of AFM images.

3.3 Nanoindentation and Related Techniques

In addition to surface topography studies, AFM can be employed to evaluate mechanical properties of sample surfaces and polymer coatings. It has already been demonstrated that force curves could be employed for this purpose. As an extension of this approach, nanoindentation, scratching or wear experiments with standard Si probes or with special diamond probes can be used.[43] There are definite advantages to these modes in comparison with similar macroscopic procedures. They are related to new mechanical measurement capabilities on the micrometer and submicrometer scales. A broad range of low forces, which can be used for nanoindentation and scratching, allows examination of thin and ultrathin coatings without the need to account for substrate influences. Another advantage of AFM use for such studies is that deformation and fracture marks are made and are evaluated with the same instrument. Although nanoindentation and scratching studies with AFM are performed in a number of industrial applications, the question of the transferability of these data to macroscopic mechanical testing has been raised and needs further investigation. Two examples, which are chosen to demonstrate nanoindentation on polymer samples, are shown below.

A matrix of indents, which were made with a diamond tip on the microlayer PE sample (see section 2.3), is shown in the height image in Figure 27(a). This image was obtained several minutes after the indents were made. From the cross-section profiles taken along the indents in neighboring layers (Figure 27b) it can be seen that the indents in a ULDPE layer are larger at the base but shallower than the indents in the high-density PE layer. The difference in the indents' base is related to differences in the elastic moduli of these layers. The differences in the indents' depth reflect partial recovery of the indents in the rubbery ULDPE layer. The combination of nanoindentation with a heating accessory looks very promising because it could allow the indents' healing to be monitored at different temperatures.

Another example of nanoindentation of two different polyimide films, which were deposited on the Si substrate by spin coating, is given in Figure 27(c) and (d). The indents were made at different tip forces and the size of the indents increases accordingly. These data can be analyzed in terms of microhardness (tens to hundreds of newtons per square millimeter range) by dividing a load on the projection area of the indent. Also the shape of the indents on these films is different. Hill locks on the

Figure 26 (a) AFM images of block copolymer PS-*b*-PMMA film, which are commonly recorded in tapping mode. Scan size 1 μm × 0.5 μm. (b) and (c) Images of PS-*b*-PMMA film obtained with *light tapping* (top) and with *hard tapping* (bottom) with (b) Si probes $k = 40\,\mathrm{N\,m^{-1}}$ and (c) with Si probe ($k = 2\,\mathrm{N\,m^{-1}}$). Scan size 0.5 μm × 0.5 μm in (b) and 0.6 μm × 0.6 μm in (c). In height images the contrast covers the 0–4-nm range.

borders of the indents, which are most pronounced in Figure 27(c), indicate plastic deformation of the polymer during indentation. Similar effects are observed in AFM images of scratches, which are made in mar studies of polymer coatings.[44]

4 HIGH-RESOLUTION IMAGING OF POLYMER STRUCTURES

Earlier AFM applications to polymer materials included studies of polymer morphologies on the micrometer and tens of micrometers scales and detection of molecular order in oriented samples and single crystals. At present, most efforts are concentrated on the imaging of polymer structures at the submicrometer scale. Such high-resolution imaging substantially complements TEM and diffraction techniques, which are used for analysis of nanometer-scale structures of polymers. In addition to imaging periodic lattices of highly drawn polymer films and single polymer crystals, these studies include visualization of individual polymer chains, the nanostructure of crystalline polymers and oriented samples, and microphase-separated morphologies of block copolymers. Although sample preparation for submicrometer AFM imaging might be nontrivial, in many cases it does not require thin sectioning, etching and staining, which is used for TEM of polymers. Direct visualization of nanometer-scale structures provided by AFM facilitates structural interpretation of the results of other characterization techniques. These data, for example, are invaluable for a correct choice of structural models employed for a rational analysis of diffraction data. However, the question of how surface structures, which are seen in AFM images of polymers, reflect their bulk structure should always be considered.

Several examples of high-resolution images are collected in this section, other examples can be found in following sections.

4.1 Visualization of Single Polymer Chains

Visualization of single DNA macromolecules deposited on different substrates was among the first exciting AFM applications.[45] Because DNA molecules of different lengths are generated in many ways, the sizing of DNA is the subject of many analytical approaches in molecular biology. For AFM studies, DNA molecules should be attached to a solid substrate first, and then imaged in air or in liquid with minimal tip–sample forces. The macromolecules appear as elongated strands in the images, Figure 28(a), and their contour length corresponds to the length of DNA as defined by the number of base pairs. Therefore, histograms that represent the contour length of the macromolecules seen in AFM images shows the molecular weight distribution of DNA. Nowadays, AFM

Figure 27 (a) Height image showing indents in multilayer PE obtained with 200-µN force. Scan size 10 µm × 10 µm. (b) Profiles of the indents. (c) and (d) Height images showing indents made in two different polyimide layers with different tip forces. Scan size 3 µm × 3 µm in both images.

is routinely used for examination of the shape and conformation of DNA strands, for observation of DNA kinks[46] and for studies of DNA–protein complexes.[47] Although the DNA length is correctly reproduced in the AFM images, its height and width cannot be determined precisely owing to tip-induced deformation and convolution of the apex shape of the tip on the macromolecule. The same is true for imaging of single polymer molecules. This problem might be resolved in the future with the introduction of sharper AFM probes and further lowering of the tip–sample force interactions.

Although AFM imaging of individual polymer macromolecules was demonstrated earlier,[41] it has only recently attracted a broad attention of researchers. The visualization of single polymer molecules and their transformation from a close-packed arrangement to an extended chain conformation was achieved in studies of single layers of PS-*b*-PMMA block copolymer. The block copolymer layer was transferred on a mica substrate from the water subphase in a Langmuir–Blodgett trough.[41] The AFM images of the complete layer of the block copolymer are shown in Figure 25. When an

incomplete layer of PS-*b*-PMMA was transferred on mica, only ''islands'' consisting of a bottom layer of condensed PMMA blocks and PS blocks on top were seen in AFM images. With an increase in humidity, chains of PMMA blocks underwent a conformational rearrangement from the close packed to the expanded, Figure 28(b). It is most likely that a thin water layer formed on the mica substrate facilitated this chain unfolding.

Visualization of polymer macromolecules is essential for characterization of novel polymers, which are synthesized for possible application in nanotechnology. Molecular conformations of monodendron-jacketed polymers have been examined by AFM.[48] The image of single macromolecules of jacketed PS, which have been deposited on a graphite substrate from a very dilute solution, is seen in Figure 29(a). The macromolecules exhibit a cylindrical shape and worm-like conformation. Alkyl chains, which are present in side groups, lead to

Figure 28 Height images of single macromolecules. (a) Double-stranded DNA deposited on mica, (b) PS-*b*-PMMA block copolymer on mica with unfolded PMMA block chains. Scan size 0.8 μm × 0.8 μm in (a) and 0.5 μm × 0.5 μm in (b).

Figure 29 (a) Height image of single chains of monodendron-jacketed PS (structure illustrated) deposited on graphite. Scan size 0.51 μm × 0.51 μm. (b) Histogram of the length distribution of monodendron-jacketed PS.

some orientation order of the macromolecules adsorbed on graphite. A histogram of the length distribution of these macromolecules has been obtained from AFM images and is shown in Figure 29(b). These data complement the molecular weight distribution obtained by size exclusion chromatography and light scattering. In particular, all these methods have been applied to studies of polymacromonomers with a methacrylate main chain and, for the first time, the length per monomer of the cylindrical brush molecules was determined in solution and in the dry state.[49]

Direct visualization of polymer chain branches (some are seen in Figure 29a) is another attractive feature offered by AFM. This analytical capability is important because of a strong dependence of polymer properties on type and amount of branching. Further expansion of AFM visualization of single polymer molecules depends to a large extent on the sample preparation, which includes a proper choice of substrate and on the deposition method for spreading single macromolecules on the substrate.

4.2 Morphology and Nanostructure of Crystalline Polymers

AFM analysis of the morphology and nanostructure of a number of crystalline polymers provides a means for better understanding their structural organization. In particular, AFM data can be employed for the rational interpretation of the results of electron microscopy and diffraction techniques. An optical micrograph and AFM images of banded spherulites of HDPE/LLDPE (linear low-density polyethylene) blends are shown in Figure 30(a–d). These structures were studied in 1959, when only optical microscopy was available.[50] Banded spherulites found in several polymers are seen in optical microphotographs as sets of concentric extension rings caused by a birefringence phenomenon, Figure 30(a). This implies an alternative orientation of PE chains in the spherulites. In other words, the molecular axis (*c* is along the chain in PE) repeatedly changes its orientation at the location of the rings. It has been shown that the chain axis spirals around the radial direction. Surface corrugations associated with the banded spherulitic patterns are seen in an AFM image of the same sample (Figure 30b). It is most likely that the sample topography with elevated ring structures is the result of extraction of amorphous material as a result of permanganate etching applied to this sample. At greater magnification, the height and phase images reveal that the lower regions consist of linear structures with a width of ca. 20 nm. They also exhibit a well-defined pitch along the main direction, Figure 30(c) and (d). These linear structures could be assigned to the edges of the lamellae. Polymer chains in these regions are oriented in a tangential direction with respect to the spherulite radius. Elevated structures actually represent the main surfaces of the lamellae, which left the bulk material and adopted a flat-on orientation on the surface being examined. In these regions PE chains are oriented perpendicular to the surface. Therefore AFM images confirm that the change in PE chain orientation is responsible for birefringence of the banded spherulite. The phase image in Figure 30(d) shows that flat lamellar surfaces exhibit a granular structure, and this structure is responsible for the appearance of the pitch along the lamellar edges.

A granular nanostructure was found in AFM images of other PEs, ranging from single crystals grown from dilute solutions to samples of ultralow-density material.[21] Most of these images were obtained on the surface of melt-crystallized samples, which were not subject to any treatment. Spherulitic morphology and nanostructure of a low-density polyethylene (LDPE) sample, which was melt-crystallized, are presented in Figure 31(a–c). A large-scale height image shows that the spherulite of LDPE is not as well developed as the one shown in Figure 30(a). The height image, which was obtained on a part of this spherulite with *light tapping*, reveals the granular structure of the LDPE surface, Figure 31(b). With the force increased, the same region in the height image in Figure 31(c) is seen as being composed of a number of fibrils. These changes are reversible, and the grain structure is restored when the force is lowered again. Actually, the height image obtained with *hard tapping* resembles typical TEM micrographs of PE samples (Figure 31d), where bright linear strips represent lamellae. Because of chemical staining applied to PE samples in TEM, which is applied to provide a contrast between regions of different density, some details of polymer nanostructure can be omitted. Therefore, AFM images, which show not only a denser core with chain folding but also PE nanostructure with a compliant grain shape that is due to a less ordered exterior, describe the crystalline architecture of polymers more accurately. In other words, the fibrils present a more rigid core of linear sequences of several grains that merge with each other. This core is made from chain-folded polymer molecules. Under appropriate crystallization conditions, chain folding of linear polymer chains will be more extensive thus leading to formation of 2D-lamellae. In particular, this happens in single crystals of polymers, whose surfaces, however, still exhibit grain substructure.[51] A tentative structural model, which describes the nanostructure of crystalline polymers, is presented in Figure 31(e).

For polymer molecules, whose geometry does not facilitate chain folding, the grain nanostructure can be dominant. One of the relevant examples is ULDPE polymer with a large number of branches. AFM images of

Figure 30 (a) Optical micrograph of banded spherulite of melt-crystallized HDPE/LLDPE blend. Area size 30 μm × 30 μm. (b) AFM height image of banded spherulite of the HDPE/LLDPE blend. Scan size 10 μm × 10 μm. (c) and (d) Height and phase images of a part of the banded spherulite. Scan size 1.5 μm × 1.5 μm.

melt-crystallized ULDPE are shown in Figure 32(a) and (b). Again, as in the case of LDPE, the grain nanostructure is seen mostly in the height image recorded with *light tapping*, Figure 32(a). When the force is increased, the same surface location is represented by a core structure which consists of relatively short lamellae or fibrils arranged into a network, Figure 32(b). This architecture is most likely to be responsible for the rubber-like behavior of this polymer. A similar nanostructure was also observed in PE with a slightly higher density of 0.87 g cm^{-3}. The changes observed in these AFM images have a reversible character.

Further evidence of the grain nanostructure of crystalline polymers is presented in images of melt-crystallized iPP, Figures 33 and 34. A large-scale height image (Figure 33a) shows iPP spherulite of the melt-crystallized sample. Part of this spherulite is presented at higher magnification in the height and phase images shown in Figure 33(b) and (c). Although there are tangential- and radial-aligned structures inside the iPP spherulite, small grains of 10–12 nm in diameter could be considered as elementary blocks of its architecture. These grains are distinctively seen in the phase image and some of them merge with neighbors to form linear tangential

Images in (b) and (c) were obtained on the same location with light and *hard tapping*, respectively. (d) TEM micrograph of PE lamellae. (Reproduced from R.L. Morgan, M.J. Hill, P.J. Barham, *Polymer*, **40**, 337 (1999).) (e) Tentative model of nanostructure of crystalline polymers.

Figure 32 Height images obtained at the same surface location of melt-crystallized ULDPE in *light tapping* (a) and in *hard tapping* (b). Scan size 0.76 μm × 0.76 μm.

and radial sequences. It is worth noting that the structures are best seen in images recorded at relatively small tip–sample interactions. As seen from the phase image, the surroundings of the grain exhibit dark contrast indicating the presence of amorphous polymer in these locations (see section 5.1). With a force increase, the individual grains are not well distinguished because of the increased tip force-induced deformation and larger tip–sample contact area. In such cases, grain sequences are seen as fibrils.

Low-force imaging helps individual grains in iPP spherulites in the crystalline samples prepared not only from melt but also from solution to be visualized. Traces of the grain nanostructure are distinguished in AFM images of epitaxially crystallized iPP samples. The morphology of epitaxially crystallized iPP on anthracene is characterized by linear structures aligned along the main crystallographic axes of the low-molecular weight crystals, Figure 34(a) and (b). At higher magnification, these structures exhibit a pitch along the main direction, Figure 34(c). The presence of granular or block nanostructure was reported in a melt-crystallized sample of syndiotactic polypropylene.[53] The nanoscale surface corrugations, which are related to the grains (blocks) gradually vanished with thermal annealing of this sample. Therefore, the fibrillar structures often present in polymer spherulites can be described as linear sequences of tightly packed grain structures, which have a common dense interior formed from chain-folded molecules. Molecular-scale AFM images obtained in contact mode reveal packing motifs of the molecules.[18]

AFM studies of crystalline polymers suggest that individual grains rather than lamellae and fibrils can be considered as the elementary building blocks of crystalline architecture. For polymer molecules, whose chain structure in not flexible enough for extensive chain folding, grains of various sizes are seen inside spherulitic structures. This is the case for copolyesters (CPESTs),[51] polyketones, poly(ethylene terephthalate)[53] and other polymers. Although grains in the nanometer size range have been found in a large number of TEM micrographs of various polymers, their unambiguous assignment to true polymer structures was not possible owing to the involvement of chemical etching or staining in the sample preparation.[54] This is not a problem for AFM imaging and the existence of grain nanostructure is no longer in question. This viewpoint is not yet the dominant one, however, it is in accordance with already known theoretical approaches and experimental data. In a polymer textbook[55] Strobl suggested that the primary step in polymer crystallization is the unmixing of crystallizable and noncrystallizable chain parts, since this necessarily has to precede the formation and growth of crystallites. This process most probably leads to the formation of an individual grain with chain folding in its interior and with a less ordered exterior. Further crystalline growth could lead to more extended fibrillar and lamellar structures.

4.3 Nanostructure of Oriented Samples

The deformation of polymers is a routine procedure that takes place during different technological processes and is used for preparation of high-performance polymeric materials with outstanding mechanical properties. Therefore, understanding the morphology and nanostructure of

Figure 33 (a) and (b) Height, and (c) phase, images of a melt-crystallized sample of iPP. Height image in (a) was obtained on 8 μm × 8 μm area. Height (b) and phase (c) images were obtained simultaneously on 1 μm × 1 μm area.

oriented materials is of great fundamental and practical importance. Again, AFM could be an invaluable addition to other techniques, which are employed in the study of oriented polymers. AFM measurements of oriented polymers have been conducted for a number of years, starting with the molecular-scale imaging of elongated PE, iPP, polybutene-I and PTFE chains.[14–17] However, the observation of individual polymer chains is not of primary interest in such applications because observation of molecular-scale defects, which define primary events in the mechanical behavior of polymers, are not accessible with AFM. Therefore, AFM studies of the nanostructure of oriented samples, which is not completely characterized by other methods is most important.

Two examples of morphology commonly found in oriented polymers are shown in Figure 35(a) and (b). They show that though the fibrillar morphology dominates in oriented materials (Figure 35a) lamellar regions oriented perpendicular to the drawing direction can often be seen. This is observed in the images of a microporous iPP membrane (Figure 22) and in the images of melt-blown polymer films, Figure 35(b). AFM images

Figure 34 AFM images of iPP epitaxially crystallized on anthracene. Height (a) and phase (b) images were obtained simultaneously on 2.4 μm × 2.4 μm area. Phase image in (c) was obtained on 650 nm × 650 nm area.

of the ultradrawn PE fibers (Spectra™ 1000), whose nanostructure is considered to be fibrillar on the basis of X-diffraction studies, revealed tiny nanofibrils of 5–7 nm in diameter.[56] These nanostructures could be described as crystallites with fully extended chain crystallites, which are responsible for the ultrahigh modulus of these materials. However, in addition to nanofibrils, a large number of different lamellar structures were also detected in the topmost layer. To improve the adhesion of such fibers to the polymer matrix in composites their surface was etched with fluorine gas and the related surface changes were distinguished in AFM images.[56]

Oriented tapes of ultrahigh-molecular weight polyethylene (UHMWPE) with different draw ratios have been extensively studied with AFM in the contact and tapping modes.[57] The fibrillar morphology of these tapes has been characterized by bundles of microfibrils with diameters in the 4–7-micron range, by individual microfibrils with diameters between 0.2 and 2 μm and nanofibrils with diameters in the 5–10-nm range. All these fibrils are oriented along the stretching direction and they are

Figure 35 (a) AFM images of uniaxially drawn PE tape (draw ratio 70) and (b) PE film drawn from melt. Scan size 0.5 μm × 0.5 μm in (a) and 1 μm × 1 μm in (b).

present in the sample bulk. Low-force imaging of the UHMWPE tapes, which was achieved in imaging under water, showed the presence of a weakly bound overlayer formed from nanofibrils (3–5 nm in diameter), which are oriented perpendicular to the stretching direction.[58]

AFM images of LLDPE film before and after uniaxial deformation are shown in Figure 36(a) and (b). The original material consists of ''islands'' of lamellar aggregates embedded into an amorphous polymer (see also section 5.1 and Figure 40). During the uniaxial stretching, plastic deformation occurs with the formation of a neck. In the necked part of the LLDPE sample, previously amorphous regions have been transformed into fibrillar domains and the lamellar aggregates were deformed in the draw direction, Figure 36(b). On further deformation all of the material becomes fibrillar.

The evolution of the crystal morphology during deformation proceeds in different ways but clarification of the polymer nanostructure and its changes during orientation is the key to a rational description of structural changes induced by deformation. In addition

Figure 36 AFM images of LLDPE film before (a) and (b) and after (c) and (d) uniaxial stretching. Scan size 20 μm × 20 μm in all images.

Figure 36 (*Continued*)

to uniaxially drawn polymer materials, biaxially oriented films have been studied with AFM. The morphology and nanostructure of biaxially oriented PVDF film is shown in Figure 37(a) and (b). The morphology is characterized by linear structures, which are aligned in the perpendicular direction. At higher magnification, tiny fibrils (3–5 nm in diameter) and shish-kebab structures have been seen in the phase images. The visualization of lamellar organization in the blown polymer films, which is achieved in AFM images (Figure 38), is of primary importance for the description of polymer orientation and its correlation with the mechanical properties of these films. Diffraction techniques, which are routinely used for these studies, require structural models for the interpretation of data. The most rational models could be built based on the AFM images, which directly show lamellar orientation. Comparative studies of biaxially oriented PE films with X-ray diffraction, electron microscopy and AFM have been performed.[59] Since then, AFM imaging has been further improved and observation of lamella structures in different polymer samples is a routine procedure.[60]

A choice of the parameters for AFM imaging is also important in studies of oriented polymer samples. Even in the contact mode, in AFM studies of oriented polymers

which were performed before the appearance of the tapping mode, the important role of the tip–sample force interactions was found. Images of the oriented film of UHMWPE (draw ratio of ~8) obtained at different tip forces are shown in Figure 39. With increased force on the nanofibrils, which are oriented along the drawing direction, regions with alternating contrast can be distinguished. Molecular-scale images taken along the fibrils reveals alternation of bright regions with extended chains with those which exhibit inferior order, Figure 39(c). These variations are of ~25 nm and correlate with the long period found in small-angle X-ray scattering (SAXS) patterns of oriented polymer samples. A structural model, which is commonly used for a description of these features, is shown in Figure 39(d). It is also consistent with AFM data. The contrast in AFM images along the nanofibrils could be explained

Figure 39 (*Continued*)

by stiffness variations, which are due to more and less regularly arranged PE chains.

The appearance of the long period contrast in high-force AFM images obtained in the contact mode was only achieved by damaging the topmost polymer layer. In tapping mode, the long-period contrast was also observed in *hard tapping*, Figure 40(a) and (b). The image changes observed on transition from *light tapping* to *hard tapping* were reversible. This means that in contrast to variable force imaging in the contact mode, observation of the long period features in the tapping mode occurs without sample damage. Here, it is worth noting that the grain nanostructure, which is seen in AFM images in a number of crystalline polymers, is of the same dimensions as the long period observed in oriented polymer samples. However, the grain nanostructure is observed only in low-force imaging and it is related to the exterior shape of the folded-chain core, whereas the long period variations are related to the alternation in order along the fibrillar core, and they are detected in high-force imaging.

5 COMPOSITIONAL IMAGING OF HETEROGENEOUS POLYMER SYSTEMS

Structural heterogeneity is a common feature of many polymer samples. This is true not only for polymer blends and block copolymers, but also for most crystalline polymers in which amorphous material is a necessary component. Only amorphous polymers such as atactic PS or PMMA could be considered as homogeneous. In characterizing heterogeneous polymer systems, knowledge of distribution of components is one of the most important properties. When applying AFM to such characterization one should realize that optimization of experimental parameters is essential for high-contrast mapping of multicomponent polymer samples. In many cases, this is achieved with *hard tapping* and the images demonstrate the distribution of individual components on the sample surface. When the probe in a polymer sample passes the viscoelastic top layer, it can penetrate into the sample and subsurface structures can be seen in the images obtained at the elevated tip forces.

The examples, which are given below, show that AFM is a powerful technique for compositional imaging of heterogeneous polymer systems.

5.1 Visualization of Amorphous and Crystalline Components

In analysis of AFM images of crystalline polymers it had been shown that the less ordered exterior surrounds close packed core in grains, fibrils and lamellae. This top layer could be described as an amorphous material bound to the crystalline structure. Traces of free-amorphous material were observed in the phase image of iPP spherulites, Figure 33(c). Additional amorphous components such as wax in industrial PE films, might dominate in surface layers. This is evident from AFM images of LLDPE blown film, which were obtained at different A_{sp}, Figure 41(a–c). In *light tapping*, only a slight surface corrugation is seen, but with the increase in the tip force the fibrillar aggregate appears more and more distinctively. Similar changes have been seen in the phase images. In this case, the probe penetrates through the topmost amorphous layer, which is in the rubber-like state at room temperature (RT). Therefore, the images at elevated forces show subsurface structures. The estimates of the tip penetration, which were made with the force curves, showed that the image in Figure 41(c) was obtained with the probe ca. 20 nm beneath the top surface.

The way a sample is prepared defines its morphology and nanostructure. Comparison of morphology of a blown LLDPE film and a LLDPE sample that was melt-crystallized with a surface facing Si substrate, is given in Figure 41(d) and (e). The phase image of the LLDPE film shows a number of lamellar aggregates embedded in an amorphous polymer. The surface of the melt-crystallized LLDPE sample is completely covered with lamellae, and some of them are seen lying flat. Both images were obtained with *hard tapping* but only for the first sample was the transition from *light* to *hard tapping* accompanied by drastic changes.

Segmented polyurethanes present structures consisting of hard and soft blocks. In such materials, phase separation may precede crystallization or occur simultaneously. AFM reveals crystalline and amorphous components in such systems.[61] The height and phase images obtained with *hard tapping* on a microtomed surface of polyurethane, which was prepared from hard blocks of MDI-butadiol (MDI-diphenylmethane diisocyanate) and soft blocks of poly(ethylene glycol), are shown in Figure 42(a–c). The height image (Figure 42a) shows traces of the microtome knife and several spherulites, which are formed of hard blocks. The spherulites are more pronounced in the phase images (Figure 42b and c), where crystalline structures (bright contrast) are seen

Figure 41 (a–c) AFM images of LLDPE film with *light*, moderate and *hard tapping*, respectively. Scan size 1.5 μm × 1.5 μm. AFM images of (d) LLDPE film and (e) melt-crystallized LLDPE sample obtained with *hard tapping*. Scan size 5 μm × 5 μm in (d) and 10 μm × 10 μm in (e).

embedded in amorphous material (dark contrast). The phase image at high magnification (Figure 42c) indicates that individual fibrils, which form the spherulites, exhibit a grain substructure.

Besides amorphous and crystalline forms many polymers also exist in a partially ordered or mesomorphic form. Such organization is common for liquid crystalline polymers and polymers with a flexible

Figure 42 (*Continued*)

(−Si−O−) backbone.[62] AFM images of several mesomorphic polysiloxanes will be discussed below and also in section 6. The height and phase images of several poly(diethylsiloxane) (PDES) patches, which were deposited on Si substrate by rubbing, are shown in Figure 43(a) and (b). The images were obtained with *hard tapping*. The height image shows striated droplets of polymer that do not wet the hydrophobic Si surface. The phase contrast indicates three different materials present on the surface. The locations of Si substrate are the brightest, whereas dark spots belong to amorphous PDES. Within the polymer droplets brighter lamellar aggregates are seen, which are oriented perpendicular to the rubbing direction. They are practically indistinguishable in the height images. The presence of extended chain organization in PDES lamellae was suggested from X-ray diffraction and electron microscopy data. Structural reorganization that occurs on heating and cooling of these samples is described in section 6.

Heterogeneity of another mesomorphic polymer, cyclolinear polysiloxane[63] is evident from the phase images recorded with *light* and *hard tapping*, Figure 43(c) and (d). Traces of planar structures, which are seen with *light tapping*, can be assigned to lamellar layers lying-flat on the sample surface. With *hard tapping*, multiple linear features of 20–30 nm in width are seen through all polymer patches. It is most likely that these features represent edges of lamellae, which exist in the sample bulk. In this case, transition from *light* to *hard tapping* led to damage of the ordered top layer.

5.2 Imaging Polymer Blends

For illustration of AFM compositional imaging of polymer blends, three types of samples were chosen. They include microlayer samples, rubber toughened plastics and binary latex blends.

A microlayer material with alternating PE layers of different density, which was described in section 2.2, Figure 7 is the most suitable sample for exploring the AFM capabilities for compositional imaging.[21] The

(c)

(d)

Figure 43 (*Continued*)

height and phase images of this sample obtained on the microtomed surface are shown in Figure 44(a) and (b). In the height image the interface borders between the wide layers of ULDPE ($\rho = 0.86\,\mathrm{g\,cm^{-3}}$) and narrow layers of PE ($\rho = 0.92\,\mathrm{g\,cm^{-3}}$) are barely distinguishable from other scratches left by an ultramicrotome knife. In the phase image these layers can be easily differentiated. The high-density layers are substantially darker than the ULDPE layers that are seen when small A_0 are used for these images. (In the phase image obtained with *hard tapping*, these layers are darker.) The high sensitivity of the phase contrast to density of PE allows the mixing of the components, which proceeds during high-temperature annealing of this blend to be monitored. The phase image obtained on the annealed sample, Figure 44(c), shows that individual fibrillar and spherulitic structures (both seen as dark strips) appear in the ULDPE layer and, especially at the interlayer interface. ULDPE does not crystallize in this fashion, therefore, this image shows that, during annealing, some polymer from the high-density PE layer diffused into ULDPE layer and crystallized when the sample was cooled.

Other effects were observed in AFM images of a microlayer blend of bisphenol A polycarbonate (PC),

(a)

(c)

Figure 44 (*Continued*)

and CPEST (Kodar™).[21] The phase images of this sample as-received after coextrusion did not exhibit any different contrast between the PC and the CPEST layers. This could be explained by the fact that the density of these polymers at RT is almost the same. However, it was possible to assign the layers to different components after thermal annealing at 200 °C. This leads to crystallization of the CPEST whereas the PC remains in an amorphous state. The height and phase images of the annealed microlayer blend are shown in Figure 45(a) and (b). The height image shows alternative layers with height variation. This topography is a consequence of sample microtomy at cryogenic temperatures. Scratches from the microtome knife are seen perpendicular to the polymer layer. Both kinds of feature are also present in unannealed microlayer samples. The main result of sample annealing is spherulitic patterns on elevated layers, which enable their identification as CPEST. The phase contrast between the crystalline and amorphous regions is much stronger than between the PC and CPEST layers (Figure 45b). This is another example showing that phase contrast is related to the density of polymer materials.

Rubber-toughened plastics and filled elastomeric systems are among the multicomponent polymer materials with a broad spectrum of practical applications. Compositional mapping of these materials is an essential part of their characterization, which helps in understanding the structure–property relationships of these materials. Initially, compositional mapping of heterogeneous polymer materials is performed in FM mode[64] and, nowadays, tapping mode with phase imaging is applied. Visualization

(a)

(b)

Figure 45 (a) and (b) AFM height and phase images of a microlayer PC/CPEST blend, which were obtained simultaneously on 50 μm × 50 μm area.

of the component distribution of a rubber-toughened blend of PC and poly(butylene terephthalate) (Xenoy™) is best achieved in images obtained with *hard tapping*, Figure 46(a) and (b). The contrast in the height image, which is mostly related to surface topography, is less informative than the phase image. The latter shows a distribution of two plastic components and rubber particles. The phase image, which was obtained with *light tapping* (not shown here), exhibits almost featureless contrast.

For many samples, the assignment of phase contrast to particular sample components is not trivial, it is rational to

Figure 46 (a) and (b) AFM height and phase images of rubber-toughened plastic, which were obtained simultaneously in *hard tapping* on a flat surface prepared with an ultramicrotome. Scan size 3 μm × 3 μm.

use a correlation installed from studies of model systems, which might have the same components in different ratios. Also a definite correlation between the phase contrast and stiffness of components can be installed from the studies of polymer materials of the same class. For example, in the phase image obtained with *hard tapping*, inorganic fillers and plastics components are typically brighter than synthetic and natural rubbers. The latter are brighter than oil and other liquid components. Identification of components can be more complicated if the number of components increases and when the fillers are in the shape of small particles, which might exhibit a local mechanical response governed by their surroundings. AFM images of a blend of natural and synthetic rubbers filled with carbon black particles are shown in Figure 47(a–c). Aggregates of carbon black, which are seen as bright patches in the phase image (Figure 47b), are the consequence of the high affinity of carbon black for synthetic rubber. Besides these aggregates, individual carbon black particles are homogeneously spread through other areas, and they are distinguished in the phase image, Figure 47(c), for the most part because of their shape.

In AFM studies of binary latex blends, a correlation between the phase contrast and glass transition temperatures (T_g) of individual components was found.[36] These binary blends are made from acrylic latexes which are different in size and exhibit different T_g. These blends were prepared from particles of latex A: 128 nm in size and $T_g = 31\,^{\circ}C$, latex B: 124 nm in size and $T_g = 11\,^{\circ}C$, and latex C: 217 nm in size and $T_g = 20\,^{\circ}C$. The height images of the A_1B_3, B_1C_3, and A_1C_2 blends (subscripts indicate a component part in the blend), which were obtained with *light tapping*, show individual particles of the surface layer, Figure 48(a), (c) and (e). The differences in T_g of the blend components are emphasized in the phase images of the same areas, which were recorded with *hard tapping*, Figure 48(b), (d) and (f). In these images, latex particles with higher T_g values always appear brighter. For

Figure 47 AFM images of a blend of natural and synthetic rubber filled with carbon black. The sample was prepared with a microtome. The images (a) and (b) were obtained simultaneoulsy in *hard tapping* on 35 μm × 35 μm area. Phase image in (c) was obtained in *light tapping*. Scan size 4 μm × 4 μm.

(b)

(c)

Figure 47 (*Continued*)

example, in the phase image of the AB blend (Figure 48b), one third of the 100-nm latex particles show up brighter which is consistent with the component ratio in this blend.

5.3 Studies of Microphase Separation in Block Copolymers

Various morphologies with microseparation of components are observed in AFM images of block copolymers. For many block copolymer samples, AFM images show microseparation patterns similar to those obtained with TEM on chemically stained ultrathin sections. With the broadening of such applications, it appears that AFM is invaluable for block copolymers with components for which it is rather difficult to find an appropriate staining agent. Though the preparation of block copolymer films for AFM usually gives a flat surface which can be directly used for imaging, the choice of imaging parameters might be nontrivial. As shown above, differentiation between the components of block copolymers is caused by different tip interactions with their blocks and the same interaction could lead to a faked, non-topography related contrast in the height images obtained in the tapping mode. Although tapping mode is the best alternative for imaging soft samples, such measurements of block copolymers should be performed with special precautions.

(a)

Figure 48 AFM images of binary latex blends A_1/B_3, B_1/C_3 and A_1/C_2, respectively. The height (a) and phase (b) images were obtained on the same 3 μm × 3 μm area of A_1/B_3 blend in *light tapping* and in *hard tapping*, respectively. The height (c) and phase (d) images were obtained on the same 3 μm × 3 μm area of B_1/C_3 blend in *light tapping* and in *hard tapping*, respectively. The height (e) and (f) images were obtained on the same 3 μm × 3 μm area of A_1/C_2 blend in *light tapping* and in *hard tapping*, respectively.

(d)

(e)

(f)

Figure 48 (*Continued*)

To illustrate this point, AFM imaging of the triblock copolymer systems, PS-*b*-PB-*b*-PS (PB, polybutadiene), will be considered. AFM images of PS-*b*-PB-*b*-PS films prepared by spin casting typically show a microphase separation of the PS and the PB blocks, where PS blocks are seen to be brighter in the height and phase images. These images are similar to TEM micrographs of the same block copolymer, which illustrates bulk film morphology. According to X-ray photoelectron spectroscopy (XPS) data and TEM micrographs, which were taken from the cross-sections cut perpendicular to the film direction, the top surface of PS-*b*-PB-*b*-PS films consists of PB blocks. To make AFM data more representative of the actual case imaging should be performed at different A_{sp}.[65] Then, AFM images obtained with *light tapping* will show the true surface topography of the top PB layer, Figure 49(a). With a decrease in A_{sp} and a corresponding increase in tip–sample force interactions, the probe will gradually penetrate through the top PB layer, which is 15–20-nm thick, and will reveal microphase separation in the subsurface material, Figure 49(b). Bright ''worms'' in this image represent stiff lamellae of PS, which is in a glassy state at RT whereas PB is in a rubber-like state. The image changes are reversible which means fast and complete recovery of the PB top layer after tip penetration. The ability of the tip to penetrate and the layer to recover are due to the rubber-like state of the top layer.

The ability of the AFM probe to penetrate through the top surface layers can be employed for layer-by-layer imaging of more complicated block copolymers. In AFM studies of a fluorinated PS-*b*-PI (PI, polyisoprene) block copolymer, in which fluorosegments are attached to PI blocks, different AFM patterns were observed during

(a)

(b)

Figure 49 AFM images of PS-*b*-PB-*b*-PS film in (a) *light* and (b) *hard tapping*. Scan size 1 μm × 1 μm.

Figure 50 AFM images of fluorinated PI-*b*-PS block copolymer film. The image in (a) was obtained in *light tapping* and the images in (b) and (c) were obtained at higher tip forces. Images in (a) and (b) were obtained on the same 0.6 μm × 0.6 μm area. Image in (c) was obtained on 3 μm × 3 μm area.

imaging at different A_{sp}, Figure 50(a–c).[66] The height image obtained with *light tapping* reveals the topography of the top layer formed by the terminal PI groups, Figure 50(a). The related phase image is featureless and is not shown here. With an increase in the tip force, a more ordered pattern appears, as seen from the phase image in Figure 50(b). The width of individual bright ''worms'' is in the 6–8-nm range. With a further increase in force, the phase image changes again and patches with different contrast are seen on the larger scale, Figure 50(c). These image changes are reversible and they indicate a complex layer-by-layer self-organization in this film. For a tentative explanation of these images, several structures were suggested,[66] however, the final conclusions could be drawn only after combined consideration of AFM images and data from other techniques.[67]

6 EXAMINATION OF POLYMER THERMAL TRANSITIONS

After the first steps in AFM characterization of polymers are done, it is important to extend the measurements

from ambient temperature to temperatures where polymer phase transitions occur. Visualization of structural changes at polymer thermal transitions could be an important addition to a number of macroscopic thermal techniques (DSC (differential scanning calorimetry), TMA (thermal mechanical analysis), DMA, etc.), that are usually employed for studying these transitions. Such studies are in their infancy and they are mostly performed at elevated temperatures.[68–71] Only a few studies were undertaken at subzero (°C) temperatures. There are two approaches towards studies of polymer phase transitions. In one approach, a polymer sample is heated or cooled, and the images at different temperatures are recorded. The images presented below were obtained in such a procedure. In another approach, the AFM probe, which stays in permanent contact with the sample, is heated and the probe deflection is monitored.[72] The probe deflection changes substantially when the probe temperature exceeds glass transition or the melting temperature of the sample. In this way, the polymer material under the probe can be recognized based on its thermal characteristics.

6.1 Imaging Polymers at Elevated Temperatures

In earlier AFM applications to polymers, when measurements at different temperatures were not possible, the effect of thermal annealing on polymer structures was examined at RT. After the initial imaging at RT, the sample was heated to the target temperature for some time and then cooled back to RT. In such procedures, morphology changes of a spin-casted PS-*b*-PB-*b*-PS film were examined. The initial morphology of the film is different from the one shown in Figure 49(b). This morphology and its changes during annealing are seen in the phase images recorded with *hard tapping*, Figure 51(a–d). As-prepared film is characterized by spherical particles and with lamellar morphology develops with annealing time, Figure 51(b–d). Long-term annealing of bulk PS-*b*-PB-*b*-PS samples leads to an appearance of ''single crystals'' formed from extended lamellae arranged into a hexagonal lattice.

With the development of heating accessories, these films were examined at various temperatures, Figure 52(a–d). It appears that in the AFM phase images, recorded under *hard tapping*, the microphase-separated patterns gradually disappear as the sample temperature approaches T_g (~100 °C) of the PS blocks. As mentioned before, the difference in mechanical properties of PS and PB blocks is responsible for the AFM contrast observed in this sample at RT. When both components of this block copolymer are in a rubber-like state, the microphase-separation pattern is not detectable with AFM. However, the presence of the microphase separation in PS-*b*-PB-*b*-PS film at these temperatures is known from the structural data obtained by other techniques.

In the imaging of fluorinated PI-*b*-PS block copolymers at temperatures below and above the smectic phase transition (ca. 50 °C)[66] the manner in which the AFM probe could detect this transition was determined, Figure 53. At temperatures below this transition, the AFM images obtained with *light* and *hard tapping* had practically the same hexagonal pattern, Figure 53(a), which indicates a ''rigidity'' of the topmost layer. The hexagonal pattern gradually disappeared with the temperature increase, Figure 53(b). At temperatures

Figure 51 AFM phase images obtained on PS-*b*-PB-PS film directly after spin casing on Si substrate (a), and after annealing at 100 °C after different times (b–d). All images were obtained at RT with *hard tapping*. Scan size 2 μm × 2 μm.

(c)

(d)

Figure 51 (*Continued*)

above 50 °C, the images obtained with *light tapping* were featureless but with an increase in the tip force a well-defined hexagonal pattern appears again, Figure 53(c) and (d). This implies that at the smectic phase transition the mobility of the top layer increases and the AFM tip can penetrate through and reach the more ordered and, therefore, more rigid structure of the underlying layer.

The first AFM studies of polymers at elevated temperatures[68] were aimed at monitoring melting and crystallization. While imaging a polymer sample around its melting point experimental difficulties should be expected related to the increased stickiness and softness of the premelted polymer even in tapping mode. This is indeed the case, and for stable imaging at elevated temperatures larger free amplitudes and lower set-point amplitudes should be used. Unfortunately, these restrictions reduce the flexibility of measurements with *light* and *hard tapping* that exists in imaging at RT.

High-temperature imaging of bulk polymer samples causes more problems than the imaging of thin and ultrathin polymer films on a solid substrate. The presence of the substrate limits of tip penetration into soft materials helps in AFM imaging. An example of such studies is given in Figure 54(a–f), where a sequence of images shows the growth of ε-PCL lamellae at a temperature ($T = 36\,^{\circ}C$) below its melting point.[39] A dendritic structure was growing inside the amorphous polymer, and the change in its dimensions can be used for evaluation of the crystallization rate. In the initial ε-PCL film, the polymer was highly crystalline, Figure 24. The sample crystallized at 36 °C exhibits a semicrystalline morphology. This morphology was stable when the sample was cooled to RT. Full crystallization was achieved only when the sample temperature was below RT, Figure 54(e) and (f). The amorphous material between the dendritic structures crystallized into thin fibrils.

6.2 Visualization of Melting and Crystallization of Polyethylene

AFM studies of melting and crystallization of ultrathin layers of different PE samples have been performed.[73] The crystalline layers of ~20 nm in thickness were formed on a Si substrate after it was dipped into a hot PE solution in xylene and taken out. The morphology of this dip-crystallized PE was characterized by 2D spherulites. The phase image in Figure 55(a) shows a part of such a spherulite formed in the LLDPE film. Almost bare substrate locations are seen in the lower left hand corner of this image. In this spherulite, most of the thin lamellae are edge-on oriented. No structural changes were detected after the sample temperature was raised to 80 °C. A further temperature increase to 125 °C (the melting temperature of this polymer in the bulk state) led to complete disappearance of PE lamellae, Figure 55(b). To detect polymer crystallization in this layer the sample temperature was lowered to 102 °C. During the first scans at this temperature, lamella structures appeared in the lower right hand corner of the imaged area, Figure 55(c). At this temperature, the crystal growth occurs relatively slowly with the formation of semicrystalline morphology, Figure 55(d). Patches of amorphous PE are seen at the edges of the area occupied initially by the spherulite. This morphology was unchanged after cooling the sample to RT.

Figure 52 AFM phase images of PS-*b*-PB-*b*-PS film at different temperatures. All images were obtained in *hard tapping*. (a) $T = 25\,^{\circ}C$, (b) $T = 80\,^{\circ}C$, (c) $T = 85\,^{\circ}C$, (d) $T = 95\,^{\circ}C$. Scan size $2\,\mu m \times 2\,\mu m$.

A more systematic AFM study of melting and crystallization was conducted on an ultrathin film of LDPE. During step-like heating of this sample (the sample temperature was increased by $5\,^{\circ}C$ increments followed by imaging) to $90\,^{\circ}C$ or to $100\,^{\circ}C$ (below the LDPE melting temperature of $115\,^{\circ}C$), the 2D spherulites disappeared and large lamella aggregates appeared, Figure 56(a) and (b). This is a consequence of LDPE recrystallization, which leads to the formation of semicrystalline morphology in the ultrathin film. Additionally, numerous holes appeared in this layer which indicates that a dewetting process has accompanied the recrystallization. Estimates of the recrystallization rate from AFM images showed non-linear character for this process, which is in contrast to PE crystallization in bulk. Such a difference is most likely to be caused by a shortage of polymer material in the ultrathin layer. Further heating of the recrystallized sample to the melting temperature of $115\,^{\circ}C$ led to the total disappearance of lamella aggregates, Figure 56(c). After cooling the melted sample to $90\,^{\circ}C$, the semicrystalline morphology with lamellar aggregates appeared again. On further cooling to RT, the

Figure 53 AFM phase images of fluorinated PI-*b*-PS at different temperatures. The images in (a–c) were obtained with *light tapping* and the image in (d) with *hard tapping*. (a) $T = 40\,^{\circ}C$, (b) $T = 49\,^{\circ}C$, (c) and (d) $T = 70\,^{\circ}C$. Scan size $2\,\mu m \times 2\,\mu m$ in (a) and (b) and $5\,\mu m \times 5\,\mu m$ in (c) and (d).

amorphous material surrounding these aggregates crystallized with formation of small lamellae, similar to the low-temperature crystallization of ε-PCL, Figure 54(e) and (f).

Structural changes, which accompany the melting of the ultrathin LDPE layer, substantially depend on the heating rate. This is demonstrated by the images in Figure 57(a) and (b), which show the morphology changes accompanied by rapidly heating the sample from RT to 90 °C. 2D spherulites were converted into sheaf-like patterns, which are embedded in amorphous surroundings. The lamellar structure seen on these sheaf-like patterns at lower temperatures gradually disappeared when the temperature was raised above 115 °C. The sheaf-like morphology remained at higher temperatures and the thickness of the sheaves increased owing to polymer dewetting of the substrate (Figure 57b). When this sample was cooled to RT, its morphology remained the same and crystallization of the sheaves led to lamellar and granular structures. A more detailed description of these changes can be found elsewhere.[73]

Figure 54 Phase images of ε-PCL layers during crystallization at 40 °C (a–d) and after complete crystallization at −30 °C (e) and (f). Scan size 4 μm × 4 μm in (a–d), 2 μm × 2 μm in (e) and 1 μm × 1 μm in (f).

Figure 55 AFM phase images of ultrathin LLDPE film at different temperatures. The image in (d) was obtained 40 min later than the image in (c). (a) $T = 25\,^{\circ}C$, (b) $T = 125\,^{\circ}C$, (c) and (d) $T = 102\,^{\circ}C$. Scan size $12\,\mu m \times 12\,\mu m$.

6.3 Monitoring of Phase Transitions in Mesomorphic Polysiloxanes

The thermal behavior of PDES is described by DSC traces shown in Figure 58. At RT, this polymer is in the mesomorphic state, and it crystallized around $0\,^{\circ}C$. Complete isotropization of this polymer is observed at temperatures above $40\,^{\circ}C$. DSC studies were performed on a bulk sample and it is expected that thermal behavior of PDES patches on Si substrate, which are examined with AFM, may be different.[71] The images in Figure 43(a) and (b) show coexistence of amorphous and lamella structures in PDES patches at RT. When PDES was deposited on the Si substrate, which was treated with argon plasma, a more complete polymer layer was formed. Lamella aggregates, which are embedded in amorphous material and are oriented perpendicular to the rubbing direction, are observed in the phase image of the PDES layer, Figure 59(a). Evident changes in the lamella morphology were observed when the sample was cooled below $0\,^{\circ}C$, Figure 59(b). These changes happened abruptly while the probe was scanning from the bottom of the area. In the higher magnification image (Figure 59c), it can clearly be seen that a linear

Figure 56 Height images of ultrathin LDPE film at different temperatures. (a) $T = 25\,^{\circ}C$, (b) $T = 100\,^{\circ}C$, (c) $T = 115\,^{\circ}C$. Scan size $10\,\mu m \times 10\,\mu m$.

substructure (with the tens of nanometers wide features) has appeared on the lamellae. The changes in lamella substructure are reversed when the sample is heated above RT, Figure 59(d). Therefore, these changes are associated with the crystallization of PDES. Visualization of these changes during crystallization from the mesomorphic state and back allows better understanding of the structural architecture of PDES. The dimensions of lamella observed in AFM images of a number of mesomorphic polysiloxanes are consistent with the extended chain organization in PDES lamella.[74] However, various nanostructures in the 20–40-nm range, which are seen in AFM images, are not completely understood. For example, the image in Figure 59(e) reveals extended nanostructures on the lamellar aggregates at the temperature of the phase transition ($T = 0\,^{\circ}C$).

The structural changes, which accompany the isotropization of PDES and low-temperature crystallization, are seen in AFM images in Figure 60(a–d). With the increased temperature lamella aggregates of the mesomorphic material gradually melt and finally disappear, Figure 60(a) and (b). The largest thermal effect is related to the crystallization of the mesomorphic material around $0\,^{\circ}C$ (Figure 58). However, this process does not involve

Figure 57 Height images of ultrathin LDPE film at different temperatures. (a) $T = 85\,^{\circ}C$, (b) $T = 126\,^{\circ}C$. Scan size $110\,\mu m \times 110\,\mu m$ in (a) and $40\,\mu m \times 40\,\mu m$ in (b).

amorphous material, which surrounds the lamella. Deep cooling of the PDES sample to $-40\,^{\circ}C$ induced crystallization of the amorphous polymer. The appearance of spherulite-like structures in the bottom right corner of Figure 60(c) and their growth (Figure 60d) can be assigned to the low-temperature crystallization of PDES. Also, new lamellae were grown from the advanced edges of large lamellae.

AFM studies of poly(dipropylsiloxane) (PDPS) at different temperatures reveal structural changes accompanying the reversible crystal–mesophase transition. PDPS differs from PDES in having slightly longer side chains and this change in chemical structure leads to the shift of the thermal phase transition to higher temperatures. At RT this polymer exists in the crystalline state, and the phase image in Figure 61(a) shows crystalline blocks with distinctive edges both of submicrometer size. Upon heating these features disappeared gradually, and in the mesomorphic state all

Figure 59 AFM phase images of PDES at different temperatures. Scan size $15\,\mu m \times 15\,\mu m$ in (a) and (b), $6\,\mu m \times 6\,\mu m$ in (c) and (d) and $2.4\,\mu m \times 2.4\,\mu m$ in (e).

Figure 59 (*Continued*)

of the surface was manifested as large lamellar bundles, which are elongated along the rubbing Y-direction, Figure 61(b) and (c). On cooling the sample back to $T = 40\,^{\circ}\mathrm{C}$, PDPS crystallization is seen as an abrupt transformation of the lamellar bundles to the crystalline blocks.

Visualization of polymer morphology and nanostructure changes at thermal phase transitions, which was demonstrated with the images ε-PCL, PE and mesomorphic polysiloxanes, opens up new capabilities for AFM in the characterization of polymers. The most exciting findings are anticipated in the examination of polymer structural changes on the submicrometer scale. Observations of morphology and nanostructure changes during recrystallization of LDPE substantially broadens our knowledge of these processes.

7 EXPECTATIONS

Applications of AFM to polymer materials have been developing progressively. Many aspects of AFM imaging

Figure 60 AFM phase images of PDES at different temperatures. Scan size 15 μm × 15 μm in (a) and (b), and 12.5 μm × 12.5 μm in (c) and (d).

of polymer samples are already understood, and the results obtained undoubtedly show the value of this technique. In its basic function, AFM provides high-resolution profiling of a surface allowing visualization of the polymer nanostructure and is an invaluable addition to other characterization techniques. However, its capabilities extend far beyond high-resolution imaging. In addition, AFM provides a means of probing of local sample properties and compositional mapping of heterogeneous polymer systems. For some samples, imaging of subsurface structures can be achieved. To realize these capabilities practically, a more thorough experimental approach should be developed, which includes all aspects of AFM analysis: sample preparation, optimization of imaging parameters and image interpretation. There is a lot of room for improvement in these features and they will be realized because of the strong interest in AFM applications of polymers both in academia and in industry. This interest will grow further because AFM complements a large number of other characterization methods. Also for microscopic studies of some polymer systems, e.g. thin

Figure 61 AFM phase images of PDPS at different temperatures. Scan size 10 μm × 10 μm in all images.

and ultrathin films, AFM is in practice the only technique applicable.

Other expectations are related to instrumental developments that broaden AFM studies of polymers. Only the first steps have been taken in AFM studies of polymers at different temperatures. The same is true of monitoring mechanically induced changes in polymer samples. An advanced picture of nanostructure organization in polymer materials, which is emerging from the combination of AFM results with data from other microscopic and diffraction techniques, will motivate researchers to explore thoroughly nanostructural changes during thermal transitions and mechanical loads.

A better understanding of the topography and structure of polymer samples that could be obtained from images recorded at different levels of tip–sample force interactions, is essential for a successful combination of surface profiling with the detection of thermal, electric, magnetic and other properties. It is challenging to map variations of these properties in polymer materials. On one hand, it is interesting to learn about these properties on the micrometer and submicrometer scales. On the other hand, to use them for recognition of individual components in heterogeneous polymer systems is also important. So far in AFM compositional mapping, variations in local mechanical or adhesive properties are employed, however, in some cases the assignment of the image contrast relating to these properties is not straightforward. This situation will improve when variations in thermal or electric properties are also recorded. It will be even more exciting to record the infrared spectrum from different locations on the submicrometer scale and in this

way to obtain ''fingerprints'' of individual polymers or their blocks. Experimental results have shown that such possibilities may be realized practically.[75]

To summarize, in the coming years researchers will explore further the advantages of new developments in AFM itself as well as in different combinations of this method with other characterization techniques. This will promote an advanced characterization of the structure and properties of polymer materials on the micrometer and submicrometer scales.

ACKNOWLEDGMENTS

Most of the AFM results included in this review were obtained at Digital Instruments in cooperation with a number of research groups worldwide.

Many thanks are due to the researchers who kindly provided polymer samples for AFM studies: Profs. E. Baer, A. Hiltner, S. Nazarenko (CWRU, Cleveland, OH), Prof V. Papkov (INEOS, Moscow, Russia), Prof V. P. Shibaev (MSU, Moscow, Russia), Dr R. Callaghan (Celgard™, Charlotte, NC), Dr B. Antrim (Rohm and Haas, Spring House, PA), Prof C. Frank (Stanford University, Stanford, CA), Prof T. Hashimoto (Kyoto University, Kyoto, Japan), Dr Soo Yeol Lee (Seoul National University, Seoul, Korea), Dr G. Capaccio (BP Chemicals, Grangemouth, Scotland), Dr A. Ghanem (Solvay, Brussels, Belgium), Prof J. McClusky (University of Texas, San Antonio, TX), Dr P. Sadhukan (Bridgestone/Firestone, Akron, OH), Dr Ch. Harrison (Princeton University, Princeton, NJ), Dr E. Sivaniah and Prof E. Kramer (UCSB, Santa Barbara, CA).

Dr S. Sheiko (Ulm University, Ulm, Germany) and Dr J. Kumaki (Toray, Japan) are gratefully acknowledged for providing original AFM images from their publications.

I greatly enjoyed my joint work with Prof Yuli Godovsky (Karpov's Institute of Physical Chemistry, Moscow, Russia) in AFM studies of a number of polymers at different temperatures, which is partly described in this paper.

My colleagues at Digital Instruments (Santa Barbara, CA) are acknowledged for sharing their everyday expertise in AFM.

Special thanks are due to Samantha Strausser (Digital Instruments) for her kind help in the preparation of this manuscript.

ABBREVIATIONS AND ACRONYMS

AFM	Atomic Force Microscopy
CPEST	Copolyester
DMA	Dynamic Mechanical Analysis
DSC	Differential Scanning Calorimetry
EFM	Electric Force Microscopy
FFT	Fast Fourier Transform
FM	Force Modulation
HDPE	High-density Polyethylene
iPP	Isotactic Polypropylene
LDPE	Low-density Polyethylene
LLDPE	Linear Low-density Polyethylene
MFM	Magnetic Force Microscopy
NMR	Nuclear Magnetic Resonance
PB	Polybutadiene
PC	Polycarbonate
PDES	Poly(diethylsiloxane)
PDPS	Poly(dipropylsiloxane)
PE	Polyethylene
PI	Polyisoprene
PMMA	Poly(methyl methacrylate)
PS	Polystyrene
PTFE	Polytetrafluoroethylene
PVDF	Poly(vinylidene fluoride)
RT	Room Temperature
SAXS	Small-angle X-ray Scattering
SCM	Scanning Capacitance Microscopy
SNOM	Scanning Near-field Optical Microscopy
SPM	Scanning Probe Microscopy
SThM	Scanning Thermal Microscopy
STM	Scanning Tunneling Microscopy
TEM	Transmission Electron Microscopy
TMA	Thermal Mechanical Analysis
UHMWPE	Ultrahigh-molecular Weight Polyethylene
UHV	Ultrahigh Vacuum
ULDPE	Ultralow-density Polyethylene
XPS	X-ray Photoelectron Spectroscopy
2D	Two-dimensional
3D	Three-dimensional
ε-PCL	Poly(ε-caprolactone)

Complex polymers are distributed in more than one direction of molecular heterogeneity. In addition to the molar mass distribution (MMD), they are frequently distributed with respect to chemical composition, functionality, and molecular architecture (see **Size-exclusion Chromatography of Polymers***). For the characterization of the different types of molecular heterogeneity it is necessary to use a wide range of analytical techniques. Preferably, these techniques should be selective towards a specific type of heterogeneity. The combination of two or more selective analytical techniques is assumed to yield multidimensional information on the molecular heterogeneity.*

The present review presents the fundamental ideas of combining liquid chromatography (LC) with other analytical techniques in multidimensional analysis schemes (see **Size-exclusion Chromatography of Polymers; Gas Chromatography in Analysis of Polymers and Rubbers; Field Flow Fractionation in Analysis of Polymers and Rubbers***). The capabilities and limitations of different coupling techniques are discussed and a number of relevant applications are given. It is shown that multidimensional structural information can be obtained when different chromatographic techniques are combined. Another approach is the hyphenation of LC with information-rich detectors. These detectors include molar mass-sensitive detection systems, such as on-line viscometry (VISC) and light scattering (LS). Information on the chemical composition of complex polymers can be obtained when spectroscopic techniques, like Fourier transform infrared (FTIR) (see* **Infrared Spectroscopy in Analysis of Polymer Structure–Property Relationships***), nuclear magnetic resonance (NMR) or mass spectrometry (MS) are coupled to LC.*

The basics and applications of multidimensional LC are addressed rather extensively. A brief introduction to different separation mechanisms is given and the particular requirements for the first and second dimensions are discussed. In conclusion, state-of-the-art examples for on-line coupled two-dimensional (2-D) chromatography are demonstrated, and future developments are reviewed.

1 INTRODUCTION

Today's polymeric materials are designed to meet very specific requirements defined by the application. Therefore, most synthetic polymers are highly complex multicomponent materials. They are composed of macromolecules varying in chain length, chemical composition, and architecture. By definition, complex polymers are heterogeneous in more than one distributed property (for example, linear copolymers are distributed in molar mass and chemical composition).

In general, the molecular structure of a macromolecule is described by its size, its chemical structure, and its architecture. The chemical structure characterizes the constitution of the macromolecule, its configuration and its conformation. For a complete description of the constitution the chemical composition of the polymer chain and the chain ends must be known. In addition to the type and quantity of the repeat units their sequence

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

of incorporation must be described (alternating, random, or block in the case of copolymers). Macromolecules of the same chemical composition can still have different constitutions due to constitutional isomerism (1,2- versus 1,4-coupling of butadiene, head-to-tail versus head-to-head coupling, linear versus branched molecules). Configurational isomers have the same constitution but different steric patterns (*cis*- versus *trans* configuration; isotactic, syndiotactic and atactic sequences in a polymer chain). Conformational heterogeneity is the result of the ability of fragments of the polymer chain to rotate around single bonds. Depending on the size of these fragments, interactions between different fragments, and a certain energy barrier, more or less stable conformations may be obtained for the same macromolecule (rod-like versus coil conformation).

Depending on the composition of the monomer feed and the polymerization procedure, different types of heterogeneities may become important. For example, in the synthesis of tailor-made polymers frequently telechelics or macromonomers are used. These oligomers or polymers usually contain functional groups at the polymer chain end. Depending on the preparation procedure, they can have a different number of functional endgroups, i.e. be mono-, or bifunctional and so forth. In addition, polymers can have different architectures, i.e. they can be branched (star- or comb-like), and they can be cyclic.

The structural complexity of synthetic polymers can be described using the concept of molecular heterogeneity, see Figure 1, meaning the different aspects of MMD, chemical composition distribution (CCD), functionality type distribution (FTD) and molecular architecture distribution (MAD). They can be superimposed one on another, i.e. bifunctional molecules can be linear or branched, linear molecules can be mono- or bifunctional, copolymers can be block or graft copolymers etc. In order to characterize complex polymers it is necessary to know the MMD within each other type of heterogeneity.

Figure 1 Schematic representation of the molecular heterogeneity of complex polymers.

Using the traditional methods of polymer analysis, such as NMR, one can determine the type and concentration of monomers or functional groups present in the sample. However, the determination of functional endgroups is complicated for long-chain molecules because of low concentration. On the other hand, these methods do not yield information on how different monomer units or functional groups are distributed in the polymer molecule. Finally, these methods in general do not provide molar mass information.

With respect to methods sensitive to the size of the macromolecule, one can face other difficulties. Size exclusion chromatography (SEC), which is most frequently used to separate polymer molecules from each other according to their molecular size in solution, must be used very carefully when analyzing complex polymers. The molecular size distribution of macromolecules can in general be unambiguously correlated with MMD only within one heterogeneity type. For samples consisting of a mixture of molecules of different functionality, the distribution obtained represents a sum of distributions of molecules having a different functionality and, therefore, cannot be attributed to a specific functionality type without additional assumptions. For the analysis of copolymers by SEC either the chemical composition along the molar mass axis must be known or detectors must be used which, instead of a concentration information, can provide molar mass information. To this end, SEC has to be coupled to composition-sensitive or molar mass-sensitive detectors.

Another option for the analysis of complex polymers is the separation with respect to chemical composition or functionality by means of interaction chromatography. In this case, functionally or chemically homogeneous fractions are obtained which then can be subjected to molar mass determination.

To summarize, for the complete analysis of complex polymers a minimum of two different characterization methods must be used. It is most desirable that each method is sensitive towards a specific type of heterogeneity. Maximum efficiency can be expected when, similar to the 2-D distribution in properties, 2-D analytical techniques are used. A possible approach in this respect is the coupling of different chromatographic modes in 2-D chromatography or the coupling of a separation technique with selective detectors, such as molar mass-sensitive or spectroscopic detectors.

2 COUPLED TECHNIQUES IN POLYMER ANALYSIS

Coupled techniques (also termed hyphenated techniques) are very frequently used in low molar mass organic chemistry. Using high-resolution chromatographic techniques, such as capillary gas chromatography (GC), gradient high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE), complex mixtures are separated into single components which are then identified by MS. By hyphenated GC/MS, HPLC/MS, and CE/MS up to several hundreds of different components can be separated and identified in one run with very high sensitivity. This is particularly important for environmental and biological samples, where frequently only very limited sample amounts are available.

Polymers are typically complex mixtures in which the composition depends on polymerization kinetics and mechanism and process conditions. To obtain polymeric materials of desired characteristics, polymer processing must be carefully controlled and monitored. Furthermore, one needs to understand the influence of molecular parameters on polymer properties and end-use performance. MMD and average chemical composition may no longer provide sufficient information for process and quality control nor define structure–property relationships. Modern characterization methods now require multidimensional analytical approaches rather than average properties of the whole sample.[1]

Different from low molar mass organic samples, where single molecules are to be determined, for complex synthetic polymers, the analytical task is the determination of a distributed property. The molecular heterogeneity of a certain complex polymer can be presented in either a three-dimensional (3-D) diagram or a so-called ''contour plot''. For a telechelic polymer these presentations are given in Figure 2. Using appropriate analytical methods, the type and concentration of the different functionality fractions must be determined and, within each functionality, the MMD has to be obtained. To do this, two different methods must be combined, each of which preferably is selective towards one type of heterogeneity. For example, a chromatographic method separating solely with respect to functionality could be combined with a molar mass selective method. Another approach would be the separation of the sample into different molar mass fractions which are then analyzed with respect to functionality.

For copolymers, in particular random copolymers, instead of discrete functionality fractions a continuous drift in composition is present, see Figure 3. To determine this chemical composition drift in interrelation with the MMD, a number of classical methods have been used, including precipitation, partition, and cross-fractionation.[2] The aim of these very laborious techniques was to obtain fractions of narrow composition and/or MMD which are then analyzed by spectroscopy and SEC.

During the last 20 years a number of techniques have been introduced in organic chemistry and applied to

Figure 2 Representation of the molecular heterogeneity of a telechelic polymer in a 3-D diagram (a) and a contour plot (b).

Figure 3 Representation of the molecular heterogeneity of a random copolymer in a 3-D diagram (a) and a contour plot (b).

polymer analysis, combining chromatographic separation with spectroscopic detection.[3] GC/MS has been used in polymer analysis,[4–11] but, due to the low volatility of high molar mass compounds it is limited to the oligomer region. The combination of pyrolysis and gas chromatography/mass spectrometry (GC/MS), however, is of great value for polymer characterization.[12,13] It provides for the analysis of complex polymers with respect to chemical composition. For a number of polymer systems characteristic low molar mass pyrolysis products are obtained, which yield information of the average composition and the ''blockiness'' of the polymer chain. Molar mass information, however, is not available from pyrolysis-GC/MS.

Much more important for polymer analysis than GC are the different techniques of LC. Using SEC, liquid adsorption chromatography (LAC), or liquid chromatography at the critical point of adsorption (LC/CC) polymers can be fractionated with respect to different aspects of molecular heterogeneity, including molar mass, functionality, and chemical composition. The advantage of these techniques over GC is that intact macromolecules are separated and analysed. As will be shown in the next sections, LC can be efficiently coupled to infrared (IR) spectroscopy,[14–19] to MS, and to NMR spectroscopy.[20,21]

Another most efficient approach is the chromatographic separation of complex polymers by combining different separation mechanisms. This can be done by coupling two chromatographs in an off-line or on-line mode. Each of these chromatographs must operate in a mode which is selective towards one type of molecular heterogeneity. This 2-D chromatography has been termed ''orthogonal chromatography'' assuming the selectivity of each separation method with respect to one distribution function, e.g. MMD, FTD, or CCD.[22] The first truly automated 2-D chromatography set-up for polymer analysis was proposed by Kilz et al.,[23] who coupled gradient HPLC and SEC.

The need for such analysis protocols results from the fact that in complex polymers in addition to chemical heterogeneity of the first kind, another type of chemical heterogeneity may exist: chemical heterogeneity of the second kind, in which polymers of different composition and chain length have similar hydrodynamic volumes and, hence, co-elute in SEC, see Figure 4.

A possible separation protocol for a complex polymer mixture is presented in Figure 5. The sample under investigation comprises molecules of different chemical compositions (different colors) and different sizes. In a first separation step this mixture is separated according to composition, yielding fractions which are chemically homogeneous. These fractions are transfered to a size-selective separation method and analyzed with respect to molar mass. As a result of this 2-D separation, information on both types of molecular heterogeneity is obtained.

3 COUPLING OF LIQUID CHROMATOGRAPHY WITH INFORMATION-RICH DETECTORS

3.1 Introduction

LC of polymers is often understood to be synonymous with SEC. SEC separates polymers according to the size of the macromolecules by entropic interactions and enables the MMD of a sample to be evaluated. However, in addition to size exclusion phenomena, other types of interaction of the macromolecules and the stationary and mobile phases of a chromatographic system can be used for separation. LAC uses enthalpic interactions to separate substances such as copolymers according to chemical composition. Finally, LC/CC can be used for functionality type separation by balancing entropic and enthalpic interactions in the chromatographic system.

Figure 5 Schematic separation protocol for the analysis of a complex polymer mixture.

SEC is the premier polymer characterization method for determining MMD. In SEC, the separation mechanism is based on molecular hydrodynamic volume. For homopolymers, condensation polymers and strictly alternating copolymers, there is a correspondence between elution volume and molar mass. Thus, chemically similar polymer standards of known molar mass can be used for calibration. However, for SEC of random and block copolymers and branched polymers, no simple correspondence exists between elution volume and molar mass because of possible compositional heterogeneity of these materials. The dimensional distribution of macromolecules can, in general, be unambiguously correlated with MMD only within one heterogeneity type. For samples consisting of molecules of different chemical composition, the distribution obtained represents an average of dimensional distributions of molecules having a different composition and, therefore, cannot be attributed to a certain type of macromolecule.

The inadequacy of using SEC without further precaution for the determination of MMD of polymer blends or copolymers results from the following consideration: for a linear homopolymer distributed only in molar mass, fractionation by SEC results in one molar mass being present in each retention volume. The polymer at each retention volume is monodisperse. If a blend of two linear homopolymers is fractionated then two different molar masses can be present in one retention volume. If now a copolymer is analyzed then a multitude of different combinations of molar mass, composition, and sequence length can be combined to give the same hydrodynamic volume. In this case, fractionation with respect to molecular size is completely ineffective in assisting the analysis of composition or MMD.

Three on-line methods are used to try to characterize copolymers by SEC with respect to MMD and composition:

- conventional SEC utilizing multiple concentration detection
- on-line analysis of SEC fractions with a LS detector.
- VISC.

The experimentally simplest approach is the combination of SEC with multiple concentration detectors. If the response factors of the detectors for the components of the polymer are sufficiently different, the chemical composition of each slice of the elution curve can be determined from the detector signals. Typically, a combination of ultraviolet (UV) and refractive index (RI) detection is used; another possibility is the use of a diode-array detector. In the case of non-UV absorbing polymers, a combination of RI and density detection yields information on chemical composition.[24–26]

The principle of dual detection is rather simple: when a mass m_i of a copolymer, which contains the weight fractions w_A and w_B ($=1 - w_A$) of the monomers A and B, is eluted in the slice i (with the volume ΔV) of the peak, the area $x_{i,j}$ of slice i obtained from detector j depends on the mass m_i (or the concentration $c_i = m_i/\Delta V$) of polymer in the slice, its composition (w_A), and the corresponding response factors $f_{j,A}$ and $f_{j,B}$, wherein j denotes the individual detector, as in Equation (1) below:

$$x_{i,j} = m_i(w_A f_{j,A} + w_B f_{j,B}) \tag{1}$$

The weight fractions w_A and w_B of the monomers can be calculated using Equation (2) below:

$$\frac{1}{w_A} = 1 - \left\{ \frac{(x_1/x_2)f_{2,A} - f_{1,A}}{(x_1/x_2)f_{2,B} - f_{1,B}} \right\} \tag{2}$$

Once the weight fractions of the monomers are known, the correct mass of polymer in the slice can be calculated using Equation (3) as follows:

$$m_i = \frac{x_i}{w_A(f_{1,A} - f_{1,B}) + f_{1,B}} \tag{3}$$

and the molar mass M_C of the copolymer is obtained by interpolation between the calibration lines of the homopolymers[27] which is given in Equation (4):

$$\ln M_C = \ln M_B + w_A(\ln M_A - \ln M_B) \tag{4}$$

wherein M_A and M_B are the molar masses of the homopolymers, which would elute in this slice of the peak (at the corresponding elution volume V_e).

It is clear that the interpolation between the calibration lines cannot be applied to mixtures of polymers (polymer blends): if the calibration lines are different, different molar masses of the homopolymers will elute at the same volume. The universal calibration is not capable of eliminating these errors, either, which originate from the simultaneous elution of two polymer fractions with the same hydrodynamic volume, but different composition and molar mass.

The architecture of a copolymer (random, block, graft) has also to be taken into account, as Revillon[28] has shown by SEC with RI, UV, and viscosity detection. Intrinsic viscosity varies largely with molar mass according to the type of polymer, its composition, and the nature of its components. Tung[29] found that for block copolymers in good SEC solvents the simpler first approach (Equation 4) is more precise.

Further information on quantitative aspects of SEC with dual detection can be obtained from Trathnigg et al.[30] Different applications of dual detection SEC in the analysis of segmented copolymers,[31] block copolymers,[32,33] star polymers,[34] and polymer blends[35,36] are also available. The limitation of SEC with dual detection is that only binary combinations of monomers can be investigated successfully. In the case of ternary combinations, more than two detectors must be used or one of the detectors must be able to detect two components simultaneously.

To overcome the problems related to classical SEC of complex polymers, molar mass-sensitive detectors are coupled to the SEC instrument. Since the response of such detectors depends on both concentration and molar mass, they have to be combined with a concentration-sensitive detector. The following types of molar mass-sensitive detectors are used frequently:[37–40]

- differential viscometer
- low angle laser light scattering (LALLS) detector
- multiangle laser light scattering (MALLS) detector.

3.2 Coupling with Molar Mass-sensitive Detectors

As has been pointed out, for SEC of complex polymers no simple correspondence exists between elution volume and molar mass. It is, therefore, useful to determine the molar mass not via a calibration curve but directly from the SEC effluent. This can be done by using molar mass-sensitive detectors based on Rayleigh LS or intrinsic viscosity measurements.[41]

In a LS detector, the scattered light of a laser beam passing through the cell is measured at angles different from zero. The (excess) intensity of the scattered light at the angle Θ ($R(\Theta)$) is related to the weight-average of molar mass M_w as expressed by Equation (5):

$$\frac{K^*c}{R(\Theta)} = \frac{1}{M_w P(\Theta)} + 2A_2c \tag{5}$$

wherein c is the concentration of the polymer, A_2 is the second virial coefficient, and $P(\Theta)$ describes the scattered light angular dependence. K^* is an optical constant containing Avogadro's constant N_A, the wavelength λ_0, the RI n_0 of the solvent, and the RI increment dn/dc of the sample. Their relationship is described by Equation (6):

$$K^* = \frac{4\pi^2 n_0^2 (dn/dc)^2}{\lambda_0^4 N_A} \tag{6}$$

In a plot of $K^*c/R(\Theta)$ versus $\sin^2(\Theta/2)$, M_w can be obtained from the intercept and the radius of gyration (R_g) from the slope. A multiangle measurement provides additional information.

In most cases the injected concentration is small and A_2 can be neglected. Thus, if the optical properties (n_0 and dn/dc) of the polymer solution are known, the molar mass at each elution volume increment can be determined as expressed by Equation (7):

$$M_{w,i} = \frac{R(\Theta)_i}{K^* P(\Theta)_i c_i} \tag{7}$$

If a low-angle LS instrument is used, $P(\Theta)$ is close to unity and $M_{w,i}$ can be calculated directly. For a multiangle LS instrument, the mean-square radius of gyration $\langle R_g^2 \rangle$ at each elution volume can also be obtained from $P(\Theta)$ as shown in Equation (8):

$$\frac{1}{P(\Theta)_i} = 1 + \frac{q^2 \langle R_g^2 \rangle_i}{3} \qquad (8)$$

$$q = \left(\frac{4\pi}{\lambda_0} \quad \sin \left(\frac{P(\Theta)}{2} \right. \right.$$

In practice, however, the radius of gyration can only be determined for molecules larger than 20 nm in diameter. By measuring radius of gyration as a function of M_w, insight into the molecular conformation of the polymer can be obtained.[1]

Molar mass determination requires the knowledge of the specific RI increment dn/dc which in the case of complex polymers depends on chemical composition. Copolymer RI increments $(dn/dc)_{copo}$ can be calculated accurately for chemically monodisperse fractions, if comonomer weight fractions w_i and homopolymer values are known, as described in Equation (9):

$$\left(\frac{dn}{dc} \right)_{copo} = \sum w_i \left(\frac{dn}{dc} \right)_i \qquad (9)$$

However, in some cases additional effects on $(dn/dc)_{copo}$ must be considered. Due to cooperative interactions between the monomer units in the polymer chain, copolymer RI increments may deviate from the summation scheme. As a result of different sequence length distributions, different $(dn/dc)_{copo}$ can be obtained for the same gross composition. Copolymer $(dn/dc)_{copo}$ values can be obtained by multiple detection SEC providing the chemical composition at each slice of the elution curve.

Unfortunately, LS investigations of copolymers are complicated even further by the fact that SEC does not separate into chemically monodisperse fractions. Accordingly, due to compositional heterogeneity the RI increment of a particular scattering center may be different from the total dn/dc of the corresponding SEC slice. Therefore, in general, only apparent molar masses for copolymers can be measured.[34] Another influencing factor is the RI of the solvent. As has been shown by Kratochvil,[42] the solvent RI should be significantly different from the values of the copolymer fractions and the corresponding homopolymers.

The evaluation of LS detectors for SEC was conducted by Jeng et al. with respect to precision and accuracy[43] and the proper selection of the LS equation.[44] The results obtained for polystyrene (PS) and polyethylene were compared for a low-angle and a multiangle LS instrument. The application of SEC/LS has been discussed in a multitude of papers. In addition to determining M_w values, the formation of microgels has been studied by Pille and Solomon.[45] Mourey and Coll investigated high molar mass PS and branched polyesters, and discussed the problems encountered in molar mass and radius of gyration determination.[46,47] Grubisic-Gallot et al. proved that SEC/LS is useful for analysing micellar systems with regard to determining molar masses, qualitative evaluation of the dynamics of unimer-micelles re-equilibration, and revealing the mode of micelle formation.[48–50]

Another very useful approach to molar mass information of complex polymers is the coupling of SEC to a viscosity detector.[51–56] The viscosity of a polymer solution is closely related to the molar mass (and architecture) of the polymer molecules. The product of polymer intrinsic viscosity $[\eta]$ times molar mass is proportional to the size of the polymer molecule (the hydrodynamic volume). Viscosity measurements in SEC can be performed by measuring the pressure drop ΔP across a capillary, which is proportional to the viscosity η of the flowing liquid (the viscosity of the pure mobile phase is denoted as η_0). The relevant parameter $[\eta]$ is defined as the limiting value of the ratio of specific viscosity $(\eta_{sp} = (\eta - \eta_0)/\eta_0)$ and concentration c for $c \to 0$, as shown by Equation (10):

$$[\eta] = \lim \frac{\eta - \eta_0}{\eta_0 c} = \lim \frac{\eta_{sp}}{c} \quad \text{for } c \to 0 \qquad (10)$$

The viscosity of a polymer solution as compared to the viscosity of the pure solvent is measured by the pressure drop ΔP across an analytical capillary-transducer system. The specific viscosity is obtained from $\Delta P/P$, where P is the inlet pressure of the system. As the concentrations in SEC are usually very low, $[\eta]$ can be approximated by η_{sp}/c.

A simple approach using one capillary and one differential pressure transducer will not work very well, because the viscosity changes $\Delta\eta = \eta - \eta_0$ will typically be very small compared to η_0, which means that one has to measure a very small change of a large signal. Moreover, flow-rate fluctuations due to pulsations of a reciprocating pump will lead to much greater pressure differences than the change in viscosity due to the eluted polymer. Instruments of this type should be used with a positive displacement pump.

A better approach is the use of two capillaries (C1 and C2) in series, each of which is connected to a differential pressure transducer (DP1 and DP2), and a sufficiently large holdup reservoir (HR) in between. With this approach, one measures the sample viscosity η from the pressure drop across the first capillary, and the solvent viscosity η_0 from the pressure drop across the second capillary. Pulsations are eliminated in this set-up, because they appear in both transducers simultaneously. Another design is that of the differential viscometer, in which four

Figure 6 Schematic representation of differential viscometers. P is inlet pressure transducer: C1–C4 are flow restriction capillaries.

capillaries are arranged in a manner similar to that of a Wheatstone bridge. In Figure 6, both designs are shown schematically.

In the ''bridge'' design, a holdup reservoir in front of the reference capillary (C4) makes sure that only pure mobile phase flows through the reference capillary, when the peak passes the sample capillary (C3). This design offers considerable advantages: the detector actually measures the pressure difference ΔP at the differential pressure transducer (DP) between the inlets of the sample capillary and the reference capillary, which have a common outlet, and the overall pressure P at the inlet of the bridge. The specific viscosity $\eta_{sp} = \Delta\eta/\eta_0$ is thus obtained from $\Delta P/P$. One concern with this type of detector is that the flow must be divided in the ratio of 1 : 1 between both arms of the bridge. This is achieved by capillaries C1 and C2, which must have a sufficiently high back pressure. Nevertheless, when a peak passes through the sample capillary, a slight deviation of the 1 : 1 ratio will be observed. A problem of flow-rate variations exists also in a single capillary viscometer: when the polymer peak passes through the measuring capillary, the increased back pressure leads to a peak shift.[57]

Being able to determine $[\eta]$ as a function of elution volume, one can now compare the hydrodynamic volumes (V_h) for different polymers. The hydrodynamic volume is, through Einstein's viscosity law, related to intrinsic viscosity and molar mass by $V_h = [\eta]M/2.5$. Einstein's law is, strictly speaking, valid only for impenetrable spheres at infinitely low volume fraction of the solute (equivalent to concentration at very low values). However, it can be extended to particles of other shapes, defining the particle radius then as the radius of a hydrodynamically equivalent sphere. In this case V_h is defined as the molar volume of impenetrable spheres which would have the same frictional properties or enhanced viscosity to the same degree as the actual polymer in solution.

Assuming the validity of this approach and in agreement with the SEC mechanism, similar elution volumes correspond to similar hydrodynamic volumes, as shown in Equation (11):

$$V_{e,1} = V_{e,2} \longrightarrow M_1[\eta]_1 = M_2[\eta]_2 \tag{11}$$

In a plot of log $(M[\eta])$ versus V_e identical calibration lines should be found for the two polymers 1 and 2, irrespective of their chemical composition. This ''universal calibration'' approach has been predicted and experimentally proved by Benoit et al.[58] As a consequence, using the universal calibration curve established with known calibration standards (for example PS), one can obtain the SEC-molar mass calibration for an unknown polymer sample.

The intrinsic viscosity is a function of molar mass given by the Mark–Houwink relationship (Equation 12), wherein K and a are coefficients for a given polymer in a given solvent at a given temperature.

$$[\eta] = KM^a \tag{12}$$

This leads to Equation (13):

$$K_1 M_1^{a(1)+1} = K_2 M_2^{a(2)+1} \tag{13}$$

If a column has been calibrated with polymer 1 (e.g. PS), the calibration line for polymer 2 can be calculated, provided that the coefficients K and a are known for both polymers with sufficient accuracy. This is shown by Equation (14):

$$\ln M_2 = \left(\frac{1}{1+a_2}\right. \ln\left(\frac{K_1}{K_2}\right. + \left(\frac{1+a_1}{1+a_2}\right. \ln M_1 \tag{14}$$

Thus, the concept of universal calibration provides an appropriate calibration also for polymers for which no calibration standards exist. The limiting factor of this approach is the accuracy of determining K and a. There are very high variations in the values reported in the literature.[59,60] Even for such common polymers as PS and polymethyl methacrylate (PMMA) the values may differ considerably.

If the Mark–Houwink coefficients are not available, a universal calibration curve is established using PS calibration standards and the SEC–viscometer combination. The basic steps involved in the MMD analysis are summarized in Figure 7. First, the universal calibration curve of the SEC separation system has to be established by using narrow molar mass standards as indicated by the top arrow pointing to the right. Once the universal calibration curve is established, one can then reverse the procedure, by going from right to left following the bottom arrow, to

Figure 7 Determination of absolute molar masses via universal SEC calibration.

obtain the molar mass calibration curve of any unknown polymer. The calibration curve is obtained literally by substracting the [η] calibration curve of the unknown sample from the universal calibration curve. The [η] calibration curve for the unknown sample is obtained from the on-line viscometer.[61]

The application of RI and differential viscometer detection in SEC has been discussed by a number of authors.[62–64] Lew et al. presented the quantitative analysis of polyolefines by high-temperature SEC and dual RI–viscosity detection.[65] They applied a systematic approach for multidetector operation, assessed the effect of branching on the SEC calibration curve, and used a signal averaging procedure to define better intrinsic viscosity as a function of retention volume. The combination of SEC with RI and viscosity detectors was used to determine molar mass and functionality of polytetrahydrofurane simultaneously.[66] Long chain branching in ethylene–propylene–diene rubber (EPDM) copolymers by SEC–viscometry was analysed by Chiantore et al.[67]

One of the difficult problems in characterizing copolymers and polymer blends by SEC–viscometry is the accurate determination of the polymer concentration across the SEC elution curve. The concentration detector signal is a function of the chemical drift of the sample under investigation. To overcome this problem, Goldwasser proposed a method where no concentration detector is required for obtaining number-average molar mass (M_n) data.[68] In the usual SEC–viscometry experiment, the determination of the intrinsic viscosity at each slice of the elution curve requires a viscosity and a concentration signal as shown by Equation (15):

$$[\eta]_i = \left(\frac{\ln \eta_{rel}}{c}\right)_i \tag{15}$$

where $\ln \eta_{rel}$ is the direct detector response of the viscometer. One calculates the molar mass averages by the expressions given in Equation (16) and in Equation (17):

$$M_n = \frac{\sum c_i}{\sum [c_i/(V_{h,x}/[\eta])_i]} \tag{16}$$

$$M_w = \frac{\sum c_i (V_{h,x}/[\eta])_i}{\sum c_i} \tag{17}$$

where $V_{h,x} = [\eta]_x M_x$ is the data retrievable from the universal calibration curve. By rearranging Equation (17) using Equation (16) the following expression (Equation 18) is obtained:

$$M_n = \frac{\sum c_i}{\sum (\ln \eta_{rel}/V_{h,x})_i} \quad \text{or}$$

$$M_n = \frac{\text{sample amount}}{\sum (\ln \eta_{rel}/V_{h,x})_i} \tag{18}$$

The sample amount can be determined easily from the injection volume and the sample concentration and no information from a concentration detector is required. With this approach, the M_n value of any polymer sample can be determined by SEC using only the viscosity detector. Other molar mass averages, however, cannot be determined. The advantage of the Goldwasser M_n method is that it can access much wider molar mass ranges than other existing methods like osmometry or endgroup methods.

Due to the problems encountered with SEC/LALLS and SEC–viscometry, a triple-detector SEC technology has been developed, where three on-line detectors are

used together in a single SEC system. In addition to the concentration detector, an on-line viscometer and a LALLS instrument are coupled to the SEC: this arrangement is known as TriSEC. With TriSEC, absolute molar mass determination is possible for polymers that are very different in chemical composition and molecular conformation. The usefulness of the TriSEC approach has been demonstrated in a number of applications. It was shown by Pang and Rudin that only by using both viscometer and LS detection are accurate MMDs obtained.[69] Wintermantel et al. have developed a custom-made multidetector instrument and demonstrated that it has great potential not only for absolute molar mass determinations but also for structure characterization of linear flexible, semiflexible, and branched polymers.[70] Degoulet et al. characterized polydisperse solutions of branched PMMA,[71] while Jackson et al. investigated linear chains of varying flexibility in order to prove universal calibration.[72] Yau and Arora discussed the advantages of TriSEC for the determination of Mark–Houwink coefficients, long-chain branching, and polymer architecture.[73]

Finally, several attempts have been made to develop an absolute molar mass detector based on osmotic pressure measurements. Commercially available membrane osmometers are designed for static measurements, and the cell design with a flat membrane is not suited for continuous flow operation. Yau[61,74] developed a detector which is different from the conventional design; it measures the flow resistance of a column caused by osmotic swelling and deswelling of soft gel particles used for the packing, see Figure 8. With a microbore gel column an M_n sensitive detector with a fast response was obtained which could be coupled to the SEC equipment. However, since the change in flow resistance could not easily be related to the osmotic pressure of the solution, absolute calibration was lost.

Recently, an osmometer based on a concentric design with a capillary-shaped membrane has been developed by Köhler et al.[75] and Lehmann et al.[76] The flow cell volume is 12.2 μL, the response time approximately 15 s, and the molar mass cut-off is below 5.000 g mol^{-1}. The design of the cell is given in Figure 9. The cylinder symmetry and stiffness of the osmometer and the favorable properties of the membrane were combined to meet the requirements for on-line detection. Testing the instrument in both batch and continuous flow operation with PS standards yielded reproducible results and good agreement with the nominal molar masses. However, the osmometer still caused a certain peak broadening, and the pressure noise level still strongly exceeded the noise of the concentration detector.

As has been discussed, the combination of SEC and molar mass-sensitive detectors is a powerful tool for the analysis of complex polymers. However, it is important to distinguish between claimed versus actual capabilities and between potential expectations and demonstrated performance. Tables 1 and 2 below, taken from a critical review of different techniques summarize the information content and additional details of SEC/LS and SEC–viscometry coupling.[61] The information content is classified into two categories. ''Primary'' information is of high precision and accuracy, insensitive to SEC operation variables, and does not require molar mass or universal calibration. ''Secondary'' information is less precise and requires calibration.

Table 1 SEC analysis using molar mass-sensitive detectors

Method	Information content	
	Primary	Secondary
Conventional SEC		MMD
SEC/LALLS	MMD	
SEC/MALLS	MMD	R_g distribution
SEC/VISC	[η] distribution	MMD R_g distribution Copolymer M_n
SEC/VISC/LS	[η] distribution MMD R_g distribution	Copolymer M_n

Table 2 Generalization of molar mass-sensitive detectors

Intended measurements	LALLS/MALLS	Viscometer
MMD	Requires precise n and dn/dc values Not affected by nonexclusion effects	Requires universal calibration and K, a-parameters
[η] distribution		Directly from experiment Not affected by nonexclusion effects
R_g distribution	MALLS only	Calculable from $[\eta]M$
Chain conformation and branching	R_g vs M plot, MALLS only	[η] vs M plot, R_g vs M plot
Chemically heterogeneous polymer analysis	Limited	Better
Noise, particulates, bubbles	Strongly affected	Less affected

In addition, the complex procedures related to SEC/LS and SEC–viscometry coupling are a potential source of error. According to Jackson and Barth[77] these include:

1. Accuracy of the universal calibration curve.
2. Detector configuration: arrangement of multiple detectors in series or in parallel can cause additional peak broadening, flow rate variations, back pressure variations.
3. Interdetector volume: detectors are placed at different physical positions and their signals must be aligned very precisely.
4. Detector sensitivity: LS and viscosity detectors are very sensitive towards higher molar masses, while the RI detector is most sensitive at lower molar masses.
5. Low molar mass fractions: polymer molecules may not adopt random coil conformation, the Mark–Houwink coefficients become functions of molar mass.

To summarize, although the principal limitation of SEC separating according to hydrodynamic volume and not molar mass cannot be overcome, the advantages of multidetector SEC in the accurate characterization of complex polymers are significant. However, in order to generate reproducible and accurate results on a routine basis, special care must be taken regarding the added complexity of the instrumentation. In addition to improving the design of multidetector SEC set-ups, important advances are expected from methods for determining the chemical composition across the MMD by interfacing SEC with FTIR spectroscopy, MS, and NMR.

3.3 Coupling with Mass Spectroscopy

From the very early stages of development of modern MS, the value of its combination with chromatography was quickly recognized. The coupling of GC with MS was a natural evolution since they are both vapor phase techniques, and very quickly GC/MS has been accepted as a standard component of the organic analytical laboratory. It has taken considerably longer to achieve a satisfactory and all-purpose mode of HPLC/MS coupling. The difficulties with HPLC/MS were associated with the fact that vaporization of typically $1\,mL\,min^{-1}$ from the HPLC translates into a vapor flow-rate of approx. $500–1000\,mL\,min^{-1}$. Other difficulties related to the eluent composition as a result of the frequent use of nonvolatile modifiers, and the ionization of nonvolatile and thermally labile analytes. However, during the past several years commercial interfaces have been developed which have led to a broad applicability of HPLC/MS.[78–80] The techniques necessary for the successful introduction of a liquid stream into a mass spectrometer are based on the following principles: electrospray ionization (ESI),[81] atmospheric pressure chemical ionization,[82] thermospray ionization,[83] and particle beam ionization.[84]

From the point of view of polymer analysis, a mass spectrometric detector would be a most interesting alternative to the conventional detectors because this detector could provide absolute molar masses of polymer components.[85,86] Provided that fragmentation does not occur, intact molecular ions could be measured. The measured mass of a particular component could then be correlated with chemical composition or chain length. However, the major drawback of most conventional HPLC/MS techniques is the limited mass range, preventing higher

oligomers (molar mass above 2000–3000 g mol^{-1}) to be ionized without fragmentation.[87–89]

The use of MS for detailed polymer analysis has become increasingly established due to the introduction of soft ionization techniques that afford intact oligomer or polymer ions with less fragmentation.[90–93] One of these techniques, ESI/MS, has been widely applied in biopolymer analysis. Proteins and biopolymers are typically ionized through acid–base equilibria. When a protein solution (the effluent from an HPLC separation) is exposed to an electrical potential it ionizes and disperses into charged droplets. Solvent evaporation upon heat transfer leads to the shrinking of the droplets and the formation of analyte ions. Larger molecules acquire more than one single charge, and, typically, a mixture of differently charged ions is obtained.

Unfortunately, up to now ESI/MS has had limited application in polymer analysis.[94,95] Unlike biopolymers, most synthetic polymers have no acidic or basic functional groups that can be used for ion formation. Moreover, each molecule gives rise to a charge distribution envelope, thus complicating the spectrum further. Therefore, synthetic polymers that can typically contain a distribution of chain lengths and have a variety in chemical composition or functionality furnish complicated mass spectra, making interpretation nearly impossible.

To overcome the difficulties of ESI/MS, Prokai and Simonsick added sodium cations to the mobile phase to facilitate ionization.[96,97] To simplify the resulting ESI spectra, the number of components entering the ion source was reduced. Prokai et al. implemented microcolumn SEC for the separation of polydisperse mixtures prior to ESI detection.[98] They used a 250 × 0.5 mm internal diameter SEC column for the molar mass separation of octylphenoxy polyethylene oxide (PEO). Applying a flow of 4 μL min, they were able to supply the effluent from the column directly into the ESI source. To promote ionization, a sheath liquid of sodium iodide in methanol was delivered to the ESI interface. Figure 10 shows a representative chromatogram and mass spectrum from the SEC/ESI analysis. The mass spectrum was obtained by averaging between 6.9 and 9.2 min. It shows singly and doubly charged molecules in the molar mass range of 1000–2000 g mol^{-1}.

The analysis of PEOs by SEC/ESI/MS with respect to chemical composition and oligomer distribution was discussed by Simonsick.[99] In a similar approach, aliphatic polyesters,[100] phenolic resins,[101] methyl methacrylate macromonomers[101] and polysulfides[102] have been analysed. The detectable mass range for different species, however, was well below 5000 g mol^{-1}, indicating that the technique is not really suited for polymer analysis.

The quantitative analysis of PMMA-butyl acrylate copolymers by coupled LC and particle beam MS has been described by Murphy et al.[103] For separation with respect to chemical composition gradient HPLC was used. The copolymer composition was determined by monitoring several low-mass fragments formed by thermal decomposition and electron impact ionization in the particle beam interface.

Matrix-assisted laser desorption/ionization (MALDI)-time-of-flight (TOF) MS is one of the newest soft ionization techniques that allows desorption and ionization of very large molecules even in complex mixtures. In

Figure 10 Micro-SEC/ESI analysis of octyloxy PEO, (a) TIC chromatogram, (b) averaged mass spectrum. (Reproduced by permission from Prokai et al.[98])

polymer analysis, the great promise of MALDI/TOF/MS is to perform the direct identification of mass-resolved polymer chains, including intact oligomers within an MMD, and the simultaneous determination of structure and endgroups in polymer samples. This most promising method for the ionization of large molecules and analysis according to their molar mass and functionality has been introduced by Karas and Hillenkamp[104,106] and by Beavis and Chait.[105] Compared to other MS techniques, the accessible mass range has been extended considerably, and the technique is fast and instrumentally very simple. Moreover, relatively inexpensive commercial instrumentation has become accessible. In principle, the sample to be investigated and a matrix solution are mixed in such a ratio that matrix separation of the sample molecules is achieved. After drying, a laser pulse is directed onto the solid matrix to photo-excite the matrix material. This excitation causes the matrix to explode, resulting in the expulsion and soft ionization of the sample molecules. Once the analyte is ionized, it is accelerated and analysed in a TOF mass spectrometer. As a result, the analyte is separated according to the molar mass of its components, and in the case of heterogeneous polymers additional information on chemical composition may be obtained. In a number of papers it was shown that polymers may be analysed up to relative molar masses of about 500 000 Da.[107–111] It was shown in a number of applications that functionally heterogeneous polymers can be analysed with respect to the degree of polymerization and the type of functional groups.[112–115]

The on-line combination of LC and MALDI/TOF/MS would be of great value for polymer analysis. In particular, for chemically or functionally heterogeneous polymers LC could provide separation with respect to chemical composition while MALDI/TOF would analyse the fractions with respect to oligomer distribution or molar mass. Unfortunately, MALDI/TOF is based on the desorption of molecules from a solid surface layer and, therefore, a priori not compatible with LC. In an attempt to take advantage of the MALDI/TOF capabilities, a number of research groups carried out off-line LC separations and subjected the resulting fractions to MALDI/TOF measurements. Although this is laborious, it has the advantage that virtually any type of chromatographic separation can be combined with MALDI/TOF.

The different options for using MALDI/TOF as an off-line detector in LC have been discussed by Pasch and Rode.[116] In SEC of low molar mass samples the separation into individual oligomers and the quantitative determination of the MMD via an oligomer calibration could be achieved, see Figure 11 for oligo(caprolactone). The lower oligomers appeared as well separated peaks at the high retention time end of the chromatogram. For the analysis of the peaks, i.e. the assignment of a certain degree of polymerization (n) to each peak, MALDI/TOF/MS was used. The SEC separation was conducted at the usual analytical scale and the oligomer fractions were collected, resulting in amounts of 5–20 ng substance per fraction in tetrahydrofuran (THF) solution. The solutions were directly mixed with the matrix solution, placed on the sample slide and subjected to the MALDI experiments. As a large number of fractions may be introduced into the mass spectrometer at one time, sample preparation and MALDI/MS measurements take a very short period of time. In total, nine fractions were collected from SEC and measured by MALDI/MS. For the lower oligomers the spectra consisted of a number of peaks of high intensity, having a peak-to-peak mass increment of 114 Da, which equals the mass of the caprolactone repeating unit. These peaks represented the $M + Na^+$ molecular ions, whereas the peaks of lower intensity in their vicinity were due to the formation of $M + K^+$ molecular ions. $M + Na^+$ and $M + K^+$ molecular ions were formed due to the presence of small amounts of Na^+ and K^+ ions in the samples and/or the matrix. Further peaks of low intensity indicated a functional heterogeneity in the samples. From the masses of the $M + Na^+$ peaks the degree of polymerization of the corresponding oligomer was calculated. By this procedure, the first peak in the chromatogram was assigned to $n = 1$, the second peak to $n = 2$, and so on. From the elution time and the degree of polymerization of each oligomer peak an oligomer calibration curve of log molar mass vs elution time was constructed. The conventional calibration curve based on PS standards differed remarkably from this oligomer calibration curve.

A much more demanding task is the analysis of fractions from LC not only with respect to molar mass but also with respect to chemical structure. The separation of a technical fatty alcohol ethoxylate (FAE) by LC, under conditions where the chain length as well as the endgroups direct the separation, is presented in Figure 12. Using this chromatographic technique, the FAE was separated into three main fractions, the first fraction appearing as one peak at a retention time of about 60 s and the second and third fractions showing oligomer separations. Fraction 1 was collected in total, whereas for fractions 2 and 3 the individual oligomer peaks were collected. The MALDI/MS spectra of all three fractions gave a peak-to-peak mass increment of 44 Da, thus indicating that all fractions consisted of species with an ethylene oxide-based polymer chain. From the masses assigned to the peaks and the peak-to-peak mass increment of the ethylene oxide repeating unit the mass of the endgroup for the different fractions was calculated. Provided the sample was a pure FAE, the endgroups of fractions 1–3 could be identified as being polyethylene glycol

Figure 11 SEC of oligo(caprolactone) and MALDI/TOF analysis of fractions (a) and SEC calibration graphs (b). (Reproduced by permission from Pasch and Rode.[116])

(PEG) (α,w-dihydroxy endgroups), C_{13}-terminated PEO (α-tridecyl-w-hydroxy endgroups) and C_{15}-terminated PEO (α-pentadecyl-w-hydroxy endgroups), respectively. Using MALDI/TOF the oligomer distribution of the PEG fraction was measured directly. For fractions 2 and 3 by determining the degree of polymerization of the oligomer peaks oligomer calibration curves were obtained, which were used for the molar mass calculation of the fractions. Thus, by combining LC and MALDI/MS detection, complex samples can be analysed with respect to chemical structure and molar mass.

Other examples of successful off-line combinations of LC and MALDI/TOF were given by Krüger et al., separating linear and cyclic fractions of polylactides by LC/CC.[117] Just and Krüger were able to separate cyclic siloxanes from linear silanols and to characterize their chemical composition.[118] The calibration of an SEC system by MALDI/TOF was discussed by Montaudo et al.[119] Polydimethyl siloxane (PDMS) was fractionated by SEC into different molar mass fractions. These fractions were subjected to MALDI/TOF for molar mass determination. The resulting peak maximum molar masses were combined with the elution volumes of the fractions from SEC to give a PDMS calibration curve log M vs. V_e. The calibration of SEC by MALDI/TOF/MS for PMMA, polyvinyl acetate and

Figure 12 Separation of a technical PEO by LC and analysis of fractions by MALDI/TOF, peak assignment indicates degree of polymerization *n*. (Reproduced by permission from Pasch and Rode.[116])

vinyl acetate copolymers has been discussed by Danis et al. In addition to obtaining proper calibration curves, band broadening of the SEC system was detected.[120] The analysis of random copolyesters has been described recently by Montaudo et al.[121]

To overcome the difficulties of the off-line analysis of SEC fractions, recently interfaces were introduced where the SEC effluent was sprayed onto a moving matrix-coated substrate. Kassis et al. used a modified LC-Transform™ SEC/FTIR interface,[122] while Nielen applied a robotic interface of Bioanalytical Instruments where the effluent was spotted on the MALDI target.[123] A novel interface for coupling SEC and MALDI/TOF has been developed recently by Lab Connections Inc.[124] In this interface, the effluent from the SEC is sprayed through a heated capillary nozzle continuously on a slowly moving MALDI target precoated with the appropriate matrix, resulting in a uniform surface layer of sample fraction and matrix. The matrix can be deposited manually or automatically on the MALDI target from an appropriate solution. When necessary, a salt is added to the matrix solution.

The characterization of PMMA by SEC/MALDI/TOF is shown in Figure 13.[125] Prior to fraction deposition the target was precoated with the matrix dithranol and a small amount of LiCl to enhance the formation of $M + Li^+$ molecular ions. Since the fraction deposition was carried out through a heated capillary nozzle, a solid fraction/matrix film was obtained on the MALDI/TOF target. The MALDI/TOF target had a length of 70 mm

Figure 13 MALDI/TOF spectra of PMMA fractions obtained from SEC/MALDI/TOF analysis. (Reproduced by permission from Pasch.[125])

and was scanned continuously with 3500 laser pulses. Every 50 pulses were summarized to give a complete MALDI/TOF spectrum. With SEC as the preseparation technique, low positions on the target correspond to high molar masses, while high positions are equivalent to low molar masses. Selected spectra from different positions of the polymer/matrix track of the PMMA sample are given in Figure 13. In the present experiment, a sample amount of 10 µg (100 µL of a 0.1 mg mL^{-1} solution) was injected into the SEC. An amount of 10% of the total effluent was sprayed onto the MALDI target, resulting in a total amount of deposited sample of 1 µg. As can be seen, for all fractions high quality spectra were obtained giving the oligomer distributions of the different fractions.

Depending on the complexity of a specific sample, MALDI/TOF is more or less capable of resolving different chemical structures. While this technique is very powerful in determining different endgroups in macromonomers and telechelics, it has its limitations when it comes to analysing copolymers. Due to the fact that the number of possible oligomers increases exponentially with the degree of polymerization, even for low molar masses very complex product mixtures are obtained which cannot be analysed solely by MALDI/TOF. In these cases it is unavoidable to combine a chromatographic prefractionation with a MALDI/TOF analysis. The usefulness of such a combination shall be demonstrated for a diblock copolymer of n-butyl methacrylate and methyl methacrylate, i.e. poly-n-butyl methacrylate (PnBMA)-b-PMMA.

The sample under investigation was prepared by group transfer polymerization (GTP) resulting in structure **(1)** which follows and is typical.

Typical spectra for fractions of different molar masses obtained from the SEC/MALDI/TOF experiment are

Figure 14 MALDI/TOF spectra of fractions obtained from SEC/MALDI/TOF analysis of a PMMA/PnBMA block copolymer. (Reproduced by permission from Pasch.[125])

(1)

given in Figure 14. The higher molar mass fractions in Figure 14(a), (b) and (c) are characteristic for copolymer structures exhibiting typical mass increments of 100 Da for the MMA repeat unit and 142 Da for the nBMA repeat unit. Even these narrow disperse fractions exhibit a multitude of different mass peaks (usually more than 100) indicating the high complexity of the fractions. The lower molar mass fraction in Figure 14(d) is very uniform with respect to composition and thus differs from the molar mass fraction in Figure 14(a), (b) and (c). For the fraction in Figure 14(d), only peak-to-peak mass increments of 142 Da were observed which are typically for PnBMA. The chemical composition of the block copolymer was studied in detail by analysing the different mass peaks (see zoomed part of the spectrum in the insert of Figure 14b). Each peak in the spectrum could be assigned to one individual oligomer composition $(nBMA)_X(MMA)_Y$.

Considering the potential of MALDI/TOF in terms of versatility and sensitivity, the direct interfacing of LC and MALDI/TOF would be a highly attractive possibility. Given the experiences with the direct introduction of small matrix-containing liquid streams into high-vacuum

Figure 15 Aerosol MALDI apparatus configured for on-line SEC/MS (a) and five spectra obtained during the separation of PEG 1000 (b). GPC, gel permeation chromatography; TEE, T-shaped flow-splitter. (Reproduced by permission from Fei and Murray.[128])

instruments, it took surprisingly long before a device for liquid introduction to MALDI was described. In some recent papers Murray and Russell[126,127] and Fei and Murray[128] discussed the on-line coupling of SEC and MALDI/TOF/MS. In an aerosol MALDI/SEC experiment, the effluent from the SEC column was combined with a matrix solution and sprayed directly into a TOF/MS. Ions were formed by irradiation of the aerosol particles with pulsed 355 nm radiation from a frequency-tripled Nd:yttrium aluminum garnet laser. The ions were mass separated in a two-stage reflectron TOF instrument, and averaged mass spectra were stored every 11 sec throughout the SEC/MS experiment. Well-resolved MALDI/TOF spectra were obtained from commercial PEG 1000 and poly(propylene glycol) (PPG) 1000, see Figure 15.

3.4 Coupling with Fourier Transform Infrared Spectroscopy

When analysing a complex polymer, very frequently the first step must be the determination of the gross composition. Only when the chemical structures of the polymer components are known can sophisticated separation techniques such as gradient HPLC or LC/CC be adapted to a specific analysis.

The most frequently used techniques for a ''flash'' analysis are IR spectroscopy and SEC. IR spectroscopy provides information on the chemical substructures present in the sample, while SEC gives a first indication of the molar mass range. Information on both molar mass and composition is obtained when SEC or a comparable chromatographic method is combined with an IR detector. In the past, numerous workers have tried to use IR detection of the SEC column effluent in liquid flow cells. The problems encountered relate to obtaining sufficient signal-to-noise (S/N) ratio even with FTIR instruments, flow-through cells with minimum path lengths and mobile phases with sufficient spectral windows. Attempts to use FTIR detection with liquid flow-through cells and high performance columns have not been very successful due to the requirement of considerably less sample concentration for efficient separation.[129–136]

A rather broad applicability of FTIR as a detector in LC can be achieved when the mobile phase is removed from the sample prior to detection. In this case the sample fractions are measured in pure state without interference from solvents. Experimental interfaces to eliminate volatile mobile phases from HPLC effluents have been tried with some success[137–139] but the breakthrough towards a powerful FTIR detector was achieved only by Gagel and Biemann, who formed an aerosol from the effluent and sprayed it on a rotating aluminum mirror. The mirror was then deposited in an FTIR spectrometer and spectra were recorded at each position in the reflexion mode.[140–142]

Recently, Lab Connections Inc. introduced the LC-Transform™, a direct HPLC/FTIR interface based on the invention of Gagel and Biemann and discussed its first applications in polymer analysis.[143–145] The design concept of the interface is shown in Figure 16. The system is composed of two independent modules, the sample collection module and the optics module. The effluent of the LC column is split with a fraction (frequently 10% of the total effluent) going into the heated nebulizer nozzle located above a rotating sample collection disc. The nozzle rapidly evaporates the mobile phase while depositing a tightly focused track of the solute. When a chromatogram has been collected on the sample collector disc, the disc is transferred to the optics module in the

Figure 16 Schematic representation of the principle of coupled LC and FTIR spectroscopy.

FTIR detector for analysis of the deposited sample track. A control module defines the sample collection disc position and rotation rate in order to be compatible with the run time and peak resolution of the chromatographic separation. Data collection is readily accomplished with software packages presently used for GC/FTIR. The sample collection disc is made from germanium which is optically transparent in the range 6000–450 cm^{-1}. The lower surface of the disc is covered with a reflecting aluminum layer.

As a result of the investigation a complete FTIR spectrum for each position on the disc and, hence, for each sample fraction is obtained. This spectrum bears information on the chemical composition of each sample fraction. The set of all spectra can be arranged along the elution time axis and yields a 3-D plot in the coordinates elution time–FTIR frequency–absorbance.

One of the benefits of coupled SEC/FTIR is the ability to identify directly the individual components separated by chromatography. A typical SEC separation of a polymer blend is shown in Figure 17.[146] Two separate elution peaks 1 and 2 were obtained, indicating that the blend contained at least two components of significantly different molar masses. A quantification of the components with respect to concentration and molar mass, however, could not be carried out as long as the chemical structure of the components is unknown.

The analysis of the chemical composition of the sample was conducted by coupled SEC/FTIR using the LC-Transform™. After separating the sample with respect to molecular size, the fractions were deposited on the germanium disc and FTIR spectra were recorded continuously along the sample track. In total, a set of about 80 spectra was obtained which was presented in a 3-D plot, see Figure 18. The projection of the

Figure 17 SEC separation of a binary blend, stationary phase: Ultrastyragel 2 × linear + 10^5 Å, eluent: THF.

Figure 18 SEC/FTIR analysis of a binary blend, ''Waterfall'' representation.

Figure 19 SEC/FTIR analysis of a binary blend, ''Contour plot'' representation.

3-D plot on the retention time–IR frequency coordinate system yielded a 2-D representation, where the intensities of the absorption peaks were given by a color code. Such a ''contour plot'' readily provides information on the chemical composition of each chromatographic fraction, see Figure 19. It was obvious that the chromatographic peaks 1 and 2 had different chemical structures. By comparison with reference spectra which are accessible from corresponding data bases, component 1 could be identified as PS, while component 2 was polyphenylene oxide. With this knowledge, appropriate calibration curves could be used for quantifying the composition and the component molar masses of the blend.

Coupled SEC/FTIR becomes an inevitable tool when blends comprising copolymers have to be analysed. Very frequently components of similar molar masses are used in polymer blends. In these cases the resolution of SEC is not sufficient to resolve all component peaks: see Figure 20 for a model binary blend containing an additive. The elution peaks of the polymer components 1 and 2 overlapped and, thus, the molar masses could not be determined directly. Only the additive peak 3 at the low molar mass end of the chromatogram was well separated and could be quantified.

A first indication of the composition of the present sample could be obtained from the contour plot in Figure 21. Component 3 showed typical absorption peaks of a phenyl benzotriazole and could be identified as a UV stabilizer of the Tinuvin type. Component 2 exhibited absorption peaks which were characteristic for nitrile groups and styrene units, while component 1 showed a strong ester carbonyl peak and peaks of styrene units. In agreement with the peak pattern of literature spectra, component 2 was identified as styrene–acrylonitrile (SAN) copolymer. Component 1 could have been a mixture of PS and PMMA or a styrene–methyl methacrylate copolymer. Since the FTIR

Figure 20 SEC separation of a blend of two copolymers and an additive, chromatographic conditions (see Figure 17).

spectra over the entire elution peak were uniform, it is more likely that component 1 was a copolymer.

One important feature of the SEC/FTIR software is that from the contour plot specific elugrams at one absorption frequency can be obtained. Taking the elugram at 2230 cm^{-1}, which is specific for the nitrile group, the elution peak of the SAN copolymer could be presented individually. For the presentation of component 1 the elugram at the carbonyl absorption frequency was drawn. Thus, via the ''chemigram'' presentation the elution peak of each component is obtained, see Figure 22.

In a relatively short period of time the LC-Transform™ system found its way into a large number of laboratories. Applications of the technique have been discussed in various fields. Willis and Wheeler demonstrated the determination of the vinyl acetate distribution in ethylene–vinyl acetate copolymers, the analysis of branching in high-density polyethylene, and the analysis of the chemical composition of a jet oil lubricant.[147] Provder et al.[148] showed that in powder coatings all additives were positively identified by SEC/FTIR through comparison of the known spectra. Even biocides could be analysed in commercial house paints. The comparison

Figure 21 Contour plot of the SEC/FTIR analysis of a blend of two copolymers and an additive.

Figure 22 Chemigrams taken from the contour plot in Figure 21.

of a PS/PMMA blend with a corresponding copolymer gave information on the chemical drift. In the analysis of a competitive modified vinyl polymer sample by SEC/FTIR some of the components of the binder could be identified readily (vinyl chloride, ethyl methacrylate and acrylonitrile), and an epoxidized drying oil additive was detected.[148] The analysis of styrene–butadiene copolymers by combining interaction chromatography and FTIR has been demonstrated.[149,150] By using LC/CC it was possible to separate block copolymers and technical rubber mixtures with respect to chemical composition. The determination of the styrene : butadiene ratio and the fine structure of the butadiene units (*cis*/*trans*-, 1,2/1,4-units) was achieved by FTIR spectroscopy.

The quality of the results from SEC/FTIR strongly depend on the surface quality of the deposited sample fractions. Cheung et al. demonstrated that the surface-wetting properties of the substrate dominate the deposit morphology[151] and the spectra fidelity, film quality, resolution and polymer recovery were considered.[152] For different interface designs it was found that the morphology of the deposited polymer film was a key parameter for quantitative measurements.

3.5 Coupling with Nuclear Magnetic Resonance Spectroscopy

NMR spectroscopy is by far the most powerful spectroscopic technique for obtaining structural information about organic compounds in solution. Its particular strength lies in its ability to differentiate between most structural, conformational and optical isomers. NMR spectroscopy can usually provide all necessary information to identify unambiguously a completely unknown compound. The NMR detection technique is quantitative with individual areas in spectra being proportional to the number of contributing nuclei. The major drawback of NMR is the relatively low sensitivity in comparison to MS, another is the fact that structure elucidation of mixtures of unknown compounds with overlapping NMR signals is difficult and may be nearly impossible in cases with overcrowding signals in a small chemical shift region of the NMR spectrum. Therefore, in many cases it would be useful that a separation is performed prior to the use of NMR. For more efficient procedures, a direct coupling of separation with NMR detection would be the method of choice.[153]

The direct coupling of LC with proton NMR has been attempted numerous times. Early experiments of coupled HPLC-^{1}H-NMR were conducted in a stop-flow mode or with very low flow rates.[154–156] This was necessary to accumulate a sufficient number of spectra per sample volume in order to improve the S/N ratio. Other problems associated with the implementation of on-line HPLC/NMR have included the need for deuterated solvents. However, with the exception of deuterium oxide the use of deuterated eluents is too expensive for routine analysis. Therefore, proton-containing solvents such as acetonitrile (ACN) or methanol must be used. To get rid of the solvent signals in the spectra, the proton NMR signals of the solvents have to be suppressed.

Recent rapid advances in HPLC/NMR provide evidence that many of the major technical obstacles have been overcome.[157,158] With the development of more powerful NMR spectrometers combined with new NMR techniques for solvent suppression it became much easier to obtain well-resolved spectra in an on-flow mode. In particular, very efficient solvent-suppression techniques significantly improved the spectra during the HPLC/NMR run.[159,160] These techniques combine shaped radio frequency pulses, pulsed-field gradients, and selective ^{13}C decoupling to acquire high-quality spectra at on-flow conditions even with high HPLC gradients. Recently, even the direct coupling of supercritical fluid chromatography (SFC) with ^{1}H-NMR[161–163] together with the monitoring of supercritical fluid extraction[164] as well as the coupling of CE and ^{1}H-NMR[165–167] have been reported. An overview of the applications of on-line HPLC-^{1}H-NMR in organic chemistry was given by Albert.[153]

The first steps of polymer analysis into coupled LC-^{1}H-NMR were performed by Hatada et al.[168] They linked a size exclusion chromatograph to a 500 MHz proton NMR spectrometer and investigated isotactic PMMA. Using deuterated chloroform as the eluent and running the chromatography at a rather low flow-rate of 0.2 mL min^{-1} they were able to accumulate well resolved proton spectra. From the intensities of the proton signals of the endgroups and the monomer units they

determined the number-average molar mass across the elution curve. In further investigations they developed an absolute calibration method for direct determination of molar masses and MMDs by on-line SEC-^{1}H-NMR.[169] Ute reported on the chemical composition analysis of EPDM copolymers as a function of molar mass, and the monitoring of stereocomplex formation for isotactic and syndiotactic PMMA.[170]

The analysis of a technical PEO with respect to chemical composition and degree of polymerization has been performed by Pasch and Hiller.[171] This investigation has been conducted under conditions which are common for HPLC separations, i.e. sufficiently high flow-rate, moderate sample concentration, and on-flow detection. Using an octadecyl-modified silica gel as the stationary phase and an eluent of ACN–deuterium oxide 50:50 (v/v) the sample was separated into different functionality fractions, see Figure 23. The major fraction of the sample eluting between 14 and 25 min exhibited a partial oligomer separation.

For structural identification of the fractions, the ^{1}H-NMR spectrometer was directly coupled via capillary tubing to the HPLC system. The injection of the sample into the HPLC system was automatically initiated by the NMR console via a trigger pulse when starting to acquire NMR data. Using an appropriate pulse sequence, both solvent resonances (ACN at 2.4 ppm and water at 4.4 ppm) could be suppressed simultaneously. As a result of the on-line HPLC/NMR experiment a contour plot of ^{1}H chemical shift vs retention time could be generated, see Figure 24. Owing to the efficient solvent suppression, the obtainable structural information relates to the entire chemical shift region. From the contour plot, four different elution peaks could clearly be identified and analysed with respect to chemical composition. The remarkable feature of this investigation was that even the low concentration components in peaks 1–3 could clearly be identified in the contour plot.

Detailed structural information could be obtained from the individual NMR spectra of the fractions at the peak maximum, see Figure 25. This also gave the relevant structures (2 and 3). The first peak was identified as being PEG while the other fractions were alkylphenoxy PEOs. From the intensities of the endgroups and the ethylene oxide repeat units the average degree of polymerization for each fraction was calculated. Based on the total intensity distribution, a calculated chromatogram (or chemigram) was generated from the NMR contour plot. Comparing the real chromatogram (Figure 23) with the chemigram (Figure 24) an excellent agreement was obtained even recalling the oligomer separation pattern of the major fraction.

Figure 23 HPLC chromatogram of a technical PEO. Stationary phase: RP-18; eluent: ACN–deuterium oxide 50:50 (v/v). (Reproduced by permission from Schlotterbeck et al.[171])

Figure 24 Contour plot of chemical shift vs. retention time and chemigram of the on-line HPLC/NMR analysis of a technical PEO. (Reproduced by permission from Pasch and Hiller.[171])

The analysis of FAE based surfactants by on-line HPLC-^{1}H-NMR has been described by Schlotterbeck et al.[172] Using a reversed stationary phase and ACN–deuterium oxide as the eluent, surfactant mixtures were separated with respect to the fatty alcohol endgroups. ^{1}H-NMR detection revealed the number of components, the chemical structure of the components, endgroups, and the chain length.

Finally, the investigation of the tacticity of oligostyrenes by on-line HPLC-^{1}H-NMR has been reported by Pasch et al.[173] The oligomer separation was carried out by hydrophobic interaction chromatography using isocratic elution with ACN on a reversed phase (RP) column RP-18. The chromatogram of an oligostyrene is shown in Figure 26. The first oligomer peak could be identified as being the dimer ($n = 2$), the next peak was identified as the trimer ($n = 3$) and, accordingly, the following peaks could be assigned to the tetramer, pentamer etc. The dimer peak appeared uniform, whereas for the following oligomers a splitting of the peaks was obtained. For $n = 3$ and $n = 4$ a splitting into two peaks was observed. For $n = 5$ and further, a splitting into three or more peaks occurred, which could be attributed to the formation of different tactic isomers.

The analysis of the isomerism of the oligomers by HPLC/NMR is given in Figure 27.[173] In this experiment conventional HPLC grade ACN was used as the eluent and no deuterium lock was applied. These conditions required high stability of the NMR instrument and a very efficient solvent-suppression technique since 100% ACN must be suppressed. The obtainable structural information related to the entire chemical shift region: however, residual signals of the eluent were obtained at 1.8–2.4 ppm and 1.3 ppm due to ACN and its impurities. The contour plot clearly revealed two signal regions, which could be used for analysis. These were the region of the methyl protons of the *sec*-butyl endgroup at 0.6–0.8 ppm and the aromatic proton region of the styrene units at 6.5–8.0 ppm. For the generation of the contour plot every 8 seconds a complete spectrum was produced by co-adding 8 scans. Accordingly, for the structural analysis 128 spectra were available over the entire retention time range. For the analysis of a separated oligomer, a minimum of four spectra could be used. These spectra bear selective information on the tacticity, even without completely separating the tactic isomers chromatographically.

As has been shown recently by Krämer et al., on-line coupled SEC-^{1}H-NMR can be used to monitor the chemical composition of random copolymers across the molar mass axis.[174] They investigated high-conversion poly(styrene-co-ethyl acrylate)s using dichloromethane as the solvent for SEC. The contour plot for a typical sample with a styrene ethyl acrylate (EA) ratio of 40 : 60 indicates that all characteristic spectral regions are accessible for analysis: see Figure 28. Residual solvent signals at 5.0–5.5 ppm do not overlap with resonances of the polymer molecules. The chemical composition across the elution peak of the copolymers is shown in Figure 29. The data were calculated from the peak

Figure 25 Individual fraction spectra taken from Figure 24. (a) NMR spectrum obtained from peak 1 in Figure 24; (b) NMR spectrum from peak 2 in Figure 24; (c) NMR spectrum from peak 3 in Figure 24; (d) NMR spectrum from peak 4 in Figure 24.

areas of the aromatic protons ($\delta = 6.5–7.3$ ppm) and the oxymethylene protons ($\delta = 3.5–4.2$ ppm) which were recorded during the SEC/NMR experiment. Owing to the low S/N ratio at the start and the end of the SEC elution curves, the chemical composition determination is less accurate than in the peak maximum. As can be seen, most of the copolymers exhibit constant chemical composition across the elution curves. This corresponds to the average chemical composition of the bulk sample. An exception is the EA-richest copolymer (styrene-EA 10.95), where at the high molar mass end of the elution curve an increased EA content is detected. At the same time, at the low molar mass end of the elution curve a strong tailing and an increased EA content is obtained. This strongly indicates that at high concentrations of EA in the monomer feed, copolymers with increased chemical and molar mass heterogeneity are obtained.

4 MULTIDIMENSIONAL LIQUID CHROMATOGRAPHY

4.1 Introduction

Despite the fact that substantial progress has been achieved in recent years in size-exclusion and interaction modes of polymer chromatography, the need and use for multidimensional separation systems has increased. The main reason for that is the fact that nowadays most classes of macromolecules posses property distributions in more than one parameter (e.g. molar mass *and* chemical composition at the same time). It is obvious that n independent properties require n-dimensional methods for accurate (independent) characterization of all those parameters. Moreover, the separation efficiency of any single separation method is limited by the efficiency and selectivity of

Figure 26 HPLC chromatogram of an oligostyrene PS 530. Stationary phase: RP-18; eluent: ACN. (Reproduced by permission from Pasch et al.[173])

the separation mode, i.e. the plate count of the column and the phase system selected. Adding more columns will not overcome the need to identify more components in a complex sample, due to the limitation of peak capacities. The peak capacity in an isocratic separation can be described, following Grushka,[175] as in Equation (19):

$$n = 1 + \frac{\sqrt{N}}{4} \ln \frac{V_p}{V_0} \tag{19}$$

The corresponding peak capacity in an n-dimensional separation is considerably higher due to the fact that

Figure 28 Contour plot of chemical shift vs retention time of the on-line SEC/NMR analysis of a random copolymer of styrene and EA. (Reproduced by permission from Krämer et al.[174])

each dimension contributes to the total peak capacity as a factor and not as an additive term for single dimension methods as described in Equation (20):

$$n_{\text{total}} = \quad n_i \sin^{(i-1)} \vartheta_i \tag{20}$$

where n_{total} represents the total peak capacity, n_i the peak capacity in dimension i and ϑ_i is the "angle" between two dimensions. The angle between dimensions is determined by the independence of the methods; a 90° angle is obtained by two methods, which are completely independent of each other and will, for example, separate two properties solely on a single parameter without influencing themselves.

In the case of a 2-D system the peak capacity is given by Equation (21):

$$\begin{aligned} n_{2D} &= n_1 n_2 \sin \vartheta \\ &= \left(1 + \frac{\sqrt{N_1}}{4} \ln \frac{V_{p,1}}{V_{0,1}} \quad \left(1 + \frac{\sqrt{N_2}}{4} \ln \frac{V_{p,2}}{V_{0,2}} \quad \sin \vartheta \right. \right. \end{aligned} \tag{21}$$

This effect is schematically illustrated in Figure 30.

Multidimensional chromatography separations can be done in planar systems or coupled-column systems. Examples of planar systems include 2-D thin-layer chromatography (TLC),[176,177] where successive 1-D TLC experiments are performed at 90° angles with different solvents, and 2-D electrophoresis, where gel electrophoresis is run in the first dimension followed by isoelectric focusing in the second dimension.[178–180] Hybrids of these systems where chromatography and electrophoresis are used in each spatial dimension were reported nearly 40 years ago.[181]

The main problem using planar methods is the difficulty in detection and collection of fractions among other

Figure 29 Chemical composition as a function of molar mass for random styrene–EA copolymers of different average composition. (Reproduced by permission from Krämer et al.[174])

less critical problems, such as homogeneous preparation of chromatographic media. However, the detection problem exists also for the coupled-column methods, mainly because of fraction dilution by each stage in a multidimensional separation system. Another aspect is the adjustment of chromatographic time bases between the different dimensions so that first dimension peaks may be sampled an adequate number of times by the next dimension separation system. This aspect has been recently studied in detail.[182]

In 2-D column chromatography systems an aliquot from a column or channel is transferred into the next separation method in a sequential and repetitive manner. Storage of the accumulating eluent is typically provided by sampling loops connected to an automated valve. Many variations on this theme exist which use various chromatographic and electrophoretic methods for one of the dimensions. In addition, the simpler ''heart cutting'' mode of operation takes the eluent from a first dimension peak or a few peaks and manually injects this into another column during the first dimension elution process. A partial compilation of these techniques has been given in several places.[182–190]

The use of different modes of LC facilitates the separation of complex samples selectively with respect to different properties like hydrodynamic volume, molar mass, chemical composition or functionality. Using these techniques in combination, multidimensional information on different aspects of molecular heterogeneity can be obtained. If, for example, two different chromatographic techniques are combined in a ''cross-fractionation'' mode, information on CCD and MMD can be obtained. Literally, the term ''chromatographic cross-fractionation'' refers to any combination of chromatographic methods capable of evaluating the distribution in size and composition of copolymers. An excellent overview on different techniques and applications involving the combination of SEC and gradient HPLC was published by Glöckner.[60]

In SEC mode the separation occurs according to the molecular size of a macromolecule in solution, which is dependent on its chain length, chemical composition, solvent and temperature. Thus, molecules of the same chain length but different composition may have different hydrodynamic volumes. Since SEC separates according to hydrodynamic volume, SEC in different eluents can separate a copolymer in two diverging directions. This principle of ''orthogonal chromatography'' was suggested by Balke and Patel.[191–193] The authors coupled two SEC instruments together so that the eluent from the first one flowed through the injection valve of the second one. At any desired retention time the flow through SEC 1 could be stopped and an injection made into SEC 2. The first instrument was operated with THF as the eluent and PS gel as the packing, whereas for SEC 2 polyether bonded-phase columns and THF–heptane were used. Both instruments utilized SEC columns. However, whereas the first SEC was operating so as to achieve conventional molecular size separation, the second SEC was used to fractionate by composition, utilizing a mixed solvent to encourage adsorption and partition effects in addition to size exclusion. Consequently, independent information on both MMD and CCD could not be obtained from such an experiment.

Figure 30 Schematic contour map representation of increased resolution and peak capacity in 2-D separations (peaks in each dimension are indicated by bars at the axes).

Since ''orthogonality'' requires that each separation technique is totally selective towards an investigated property, it seems to be more advantageous to use a sequence of methods, in which the first dimension separates according to chemical composition. In this way quantitative information on CCD can be obtained and the resulting fractions eluting from the first dimension are chemically homogeneous. These homogeneous fractions can then be analyzed independently in SEC mode in the second dimension to get the required MMD information. In such cases, SEC separation is strictly separating according to molar mass, and quantitative MMD information can be obtained.

Examples illustrating the potential of multidimensional separations will be given in section 4.5.

Figure 31 General experimental set-up for an 2-D chromatography system.

4.2 Experimental Aspects of Multidimensional Separations

Setting up a 2-D chromatographic separation system is actually not as difficult as one might think at first. As long as well-known separation methods exist for each dimension the experimental aspects can be handled quite easily in most cases. Off-line systems just require a fraction-collection device and something or someone who reinjects the fractions into the next chromatographic dimension. In on-line 2-D systems the transfer of fractions is preferentially done by automatic injection valves as was proposed by Kilz et al.[23,188,194] Figure 31 shows a general set-up for an automated 2-D chromatography system.

The focal point in 2-D chromatography separations is the transfer of fractions eluting from the first dimension into the second dimension. This can be done in various ways. The most simplistic approach is by collecting fractions from one separation and manually transferring them into the second separation system. Obviously, this approach is prone to many errors, labor intensive and quite time-consuming. A more efficient way of fraction transfer can be achieved by using electrically (or pneumatically) actuated valves equipped with two injection loops. Such a set-up allows one fraction to be injected and analyzed from one loop while the next fraction is collected at the same time in the second loop (see Figure 32). Total mass transfer from the first to the second dimension can be guaranteed by proper selection of flow rates in both dimensions.[195] This is a very beneficial situation as compared to heart-cut transfers, since by-products and trace-impurities can be separated even if they are not visible (VIS) in the first dimension separation. Table 3 shows a summary of potential fraction transfer options.

Figure 32 Fraction transfer between chromatography dimensions using a dual-loop 8-port valve.

There are some other important aspects which have to be considered for optimum 2-D experiment design.

4.2.1 Selection of Separation Techniques

Despite the fact that, historically, planar chromatography played an important role in multidimensional separations, this article will not discuss these aspects because they represent the past. The foreseeable future is with column-based techniques, which allow a well-controlled transfer of samples between different methods.

Obviously, destructive methods like GC and SFC, which destroy the chromatographic phase system, play a more limited role in multidimensional separations as they can only be used in the last separation step.

Schure recently published a theoretical paper[196] which discussed different chromatographic method combinations on the basis of efficiency, sample dilution and detectability. He investigated CE, GC, LC, SEC and field-flow fractionation (FFF) in detail, while omitting other methods, which are potential candidates for method hyphenation, such as SFC and temperature-rising elution fractionation (TREF).

Schure highlights several universal experimental factors (including plate count, injection volume, injected mass and injection band dilution), which should be taken into account when designing multidimensional separations. Table 4 summarizes Schure's results for the applicability of a given method in a multidimensional experiment. It is obvious that a low resolution, low injected mass method with high dilution of the

Table 3 Summary of 2-D transfer injection options

Transfer	Mode	Advantages	Disadvantages	Example
Manual	Off-line	Very simple Fast set-up	Time-consuming Not for routine work Not precise No correlation of fraction elution to transfer time Not quantitative	Test tube
Automatic	Off-line	Simple Easy Fast set-up	Less precise No correlation of fraction elution to transfer time Not quantitative	Fraction collector storage valve
Single-loop	On-line	Correct concentrations Correct transfer times Automation	Transfer not quantitative Set-up time	Injection valve (with actuation)
Dual-loop	On-line	Correct concentrations Correct transfer times Quantitative transfer automation	Set-up time Special valve	8-port actuated valve Combination of 2 conventional 6-port injection valves

Table 4 Synopsis of typical conditions and dilution factors in 1-D separations (Schure[196])

Separation mode	Experimental parameters				Result Dilution f
	dimensions (mm)	d_p (μm)	N (1 col^{-1})	V_{inj} (μl)	
GC	2500 × 0.25	n/a	125 000	1	26.2
LC	250 × 4.6	5	10 000	10	25.1
SEC	300 × 8.0	5	10 000	100	6.54
FFF	600 × 2 × 0.002	n/a	651	2	1340
CE	400 × 0.05	n/a	100 000	4.9e−4	12.7

Table 5 Calculated dilution factors for 2-D separations (Schure[196]) assuming splitless transfer injections (experimental conditions similar to those of Table 4)

1-D \ 2-D	GC	LC	SEC	FFF	CE[a]
GC	226	n/a	n/a	n/a	n/a
LC	217	141	113	4120	43.7
SEC	56.4	36.6	29.4	1070	11.4
FFF	11 600	7500	6030	220 000	2230
CE[b]	28	18.2	14.6	533	5.7

[a] Splitless transfer injections very difficult.
[b] Transfer concentrations very small.

injection band is a poor candidate for a multidimensional experiment.

Schure also calculated parameters to estimate the potential of 2-D method combinations. Results for splitless transfer injections are given in Table 5. CE, LC and SEC were rated best. This theoretical result agrees very well with experimental results and the actual number of published papers on 2-D separations. The most widely used method combination currently is that of LC with SEC.

4.2.2 Sequence of Separation Methods

This is an important aspect in order to get the best resolution and most accurate determination of property distributions. It is advisable to use the method with highest selectivity for the separation of one property as the first dimension. This ensures the highest purity of eluting fractions being transfered into the subsequent separation. In the case of gradient HPLC and GPC as separation methods, authors of early publications[191–193,197,198] used GPC as the first separation, because it took much longer than a subsequent HPLC analysis. This is not the best set-up, however, because the GPC fractions are only monodisperse in hydrodynamic volume, not in molar mass, chemical composition, etc. On the other hand, HPLC separations can be fine-tuned using gradients to fractionate only according to a single property, which can then be characterized for molar mass without any bias.

In many cases, interaction chromatography as the first dimension separation method is the best and most adjustable choice. From an experimental point of view, high flexibility is required for the first chromatographic dimension. In general, this is also more easily achieved when running the interaction chromatography mode in the first dimension, because:

(i) More parameters (mobile phase, mobile phase composition, mobile phase modifiers, stationary phase, temperature etc.) can be used to adjust the separation according to the chemical nature of the sample.

(ii) Better fine-tuning in interaction chromatography allows for more homogeneous fractions.

(iii) Sample load on such columns can be much higher as compared to SEC columns, for instance.

4.2.3 Detectability and Sensitivity in the Second Dimension

Because of the consecutive dilution of fractions, detectability and sensitivity become important criteria in 2-D experiment design. If byproducts and trace impurities have to be detected, only the most sensitive and/or selective detection methods can be employed. Evaporative light scattering detection (ELSD), despite several drawbacks, has been used mostly due to its high sensitivity for compounds which will not evaporate or sublime under detection conditions. Fluorescence and diode array UV/VIS are also sensitive detection methods, which can pick up samples at nanogram level. Mass spectrometers have a high potential in this respect too: however, they are currently not developed to a state where they would be generably usable.

Only in rare cases has RI detection, otherwise very popular in SEC, been used in multidimensional separations, because of its low sensitivity and strong dependence on mobile phase composition.

As a general rule, the higher the inject band dilution of a given separation method the more sensitive a subsequent detection method has to be. Such type of model calculations can be done easily; refer to Table 4 in section 4.2.1 and the paper by M. Schure[196] for further details.

4.2.4 Other Experimental Factors Affecting Multidimensional Separations

Depending on the specific type of the multidimensional experimental set-up, there are a number of other parameters to control and care about. Some are listed here, but because they are specific to the method combination, this list reflects only those techniques in most common use.

4.2.4.1 Influence of Eluent Transfer from First to Second Dimension A very important aspect in multidimensional chromatography design is the compatibility of mobile phases which are transferred between the different dimensions. It is a necessity that the mobile phases in two consecutive stages in multidimensional separations are completely miscible. Otherwise the separation in the second method is dramatically influenced and the fraction transfer is restricted or completely hindered. In gradient

systems, this requirement has to be verified for the total composition range.

In SEC separations the transfer of mixed mobile phases can affect molar mass calibration. In order to get proper molar mass results, the calibration curves have to be measured using the extremes of mobile phase composition and tested for changes in elution behavior and pore-size influence in the SEC column packing. The better the thermodynamic property of the SEC eluent, the less influence is expected on the SEC calibration when the transfer of mobile phase from the previous dimension occurs. It has been shown to be advantageous to use the SEC eluent as one component of the mobile phase in the previous dimension to avoid potential interference and mobile phase incompatibility.

4.2.4.2 Time Consumption Time is an important issue when designing multidimensional experiments. Set-up time itself plays only a lesser role, but the time needed for the multidimensional separations themselves can be considerable. This is especially true for 2-D separations using quantitative mass transfer via tandem-loop transfer valves. Heart-cut experiments require much less time and are often sufficient to check out the applicability of the approach. Cutting down on time consumption for multidimensional experiments is currently a heavily investigated topic. Several approaches are investigated and allow investigators to be optimistic and reduce experiment times by a factor of about 10 for complete mass transfer experiments using optimized column sets and flow conditions.

Another time requirement in multidimensional separations is that needed to reduce the amount of data and present them in an instructive way. With several dozen transfers between dimensions, data reduction and presentation can be very time-consuming and has been a real burden for those who performed the first cross-fractionation experiments.[191–193,198] There is a clear need for specialized multidimensional software which does all the data acquisition, fraction transfer, valve switching, data reduction, data consolidation and presentation of results. Currently, there is only one 2-D chromatography system commercially available[23,199] which is widely used. A few laboratories use in-house solutions, which are specific to their own chromatography and data capture hardware and specific also to result calculation and report creation.

4.3 Separation Techniques for the First Dimension

For an in-depth description of individual separation techniques used for multidimensional separations, please refer to the respective sections in this encyclopedia. This chapter deals with the specific aspects of the separation methods, which will help the reader to understand how to select one of them for a given multiple separation experiment.

4.3.1 Liquid Chromatography

This is the most often used technique for multidimensional separations. LC can be performed in normal phase or RP systems using isocratic or gradient elution. There is an abundance of stationary phases with different types of surface modifications of different polarities. This flexibility in experimental parameters is a very important consideration when using LC as a first dimension method, since it can be fine-tuned to separate according to a given property more easily than most other chromatographic techniques.

Gradient HPLC has been useful for the characterization of copolymers.[200–204] In such experiments careful choice of separation conditions is imperative. Otherwise, low resolution for the polymeric sample will obstruct the separation. On the other hand, the separation in HPLC, dominated by enthalpic interactions, perfectly complements the entropic nature of the SEC retention mechanism in the characterization of complex polymer formulations.

LC separation is based on an enthalpic interaction between the solute and the ''surface'' of the stationary phase. In pure interactive LC separations entropic contributions to the retention are absent. The distribution coefficient K_d can be derived from basic thermodynamics and can be measured from the activity of the analyte in the mobile (a_m) and stationary (a_s) phase as shown in Equation (22):

$$K_d(\mathrm{LC}) = \frac{a_s}{a_m} = e^{-\frac{\Delta H}{RT}} \tag{22}$$

The enthalpy change of the analyte corresponds to dispersion, polarization and charge-transfer interactions as well as H-bonding and ion exchange. Obviously, the distribution coefficient is larger than unity in LC separations.

The retention in pure LC separations can be calculated according to Equation (23):

$$V_e = V_0 + K_d(\mathrm{LC})V_{\mathrm{pore}} \tag{23}$$

The absence of entropic contributions to the separation is only possible if the stationary phase consists of nonporous beads or if the analyte molecules cannot penetrate into any pore in the stationary phase because of their size or interaction energy (e.g. ionic repulsion). In general, it will not be possible to avoid entropy changes in LC experiments with samples of different molar masses or sizes. In such cases it is best to select either a column which has very small or very large pores, which will force

the molecules to be excluded totally from the stationary phase or to permeate totally the pores of the packing. In both situations entropic contributions to the separation can be minimized.

In the general case, the distribution coefficient can be written as in Equation (24):

$$K_d = \frac{a_s}{a_m} = e^{-\frac{\Delta G}{RT}} = e^{-\frac{\Delta H}{RT}} e^{\frac{\Delta S}{R}} = K_d(\mathrm{LC})K_d(\mathrm{SEC}) \quad (24)$$

The elution in mixed-mode LC separations can be calculated according to Equation (25):

$$V_e = V_0 + [K_d(\mathrm{LC})K_d(\mathrm{SEC})]V_{pore} \quad (25)$$

This equation describes the general behavior of solutes in porous stationary phases. However, the dominant separation mechanism in LC with entropic contributions is the enthalpy term.

It is interesting to study the retention dependence on molar mass in LC separations. This is especially important when applying this technique to macromolecules, where chain statistics, chemical composition and molecular size play an important role in chromatographic behavior. Figure 33 shows the adsorption characteristics of molecules of different chain length or molar mass. The adsorption process is determined by the interaction enthalpy which itself is governed by active sites on the analyte molecule. If molecules are small only very few interactive sites are present, which may differ in nature and possess different interaction energies. In such cases, retention is relatively small (K_d less than about 10). Larger molecules, especially macromolecules, are composed of repeating units (usually called monomers), which can totally adsorb on the column packing. This is due to the fact that each and every repeating unit can potentially interact with the chromatographic surface. The longer the chains get, the higher the total interaction enthalpy and the higher the retention time to elude from the column (see Figure 33).

Figure 33 Adsorption of macromolecules of different molar mass on interactive LC columns.

The statistics of chain adsorption are determined by the magnitude of the entropy loss of the adsorbed macromolecule. If the entropy loss of the chain is small as compared to the adsorption enthalpy gain, the molecules will completely attach to the surface and the Gaussian chain will collapse into a 2-D layer. This scenario will dominate in cases where the solutes contain functional groups with strong interactions and where the eluent strength is relatively poor. In cases where the adsorption energy is relatively small, the entropy loss due to adsorption can be larger than the enthalpy gain. The chain only attaches selectively at the surface on the column packing forming loops. In such cases the macromolecules can desorb again. The adsorption/desorption process can be controlled by the nature of the stationary phase or even more easily by the thermodynamic properties of the eluents and gradient composition. Recently, temperature was also used to moderate adsorption behavior in chromatography.[205] Details of chain statistics in adsorption chromatography can be found in the book by Glöckner.[206]

4.3.2 Liquid Chromatography at the Critical Point of Adsorption

In LC and SEC chromatography modes either the enthalpy or the entropy dominate the separation. Several years ago Russian scientists found that homopolymers of different molar mass show exactly identical retention behavior on TLC plates[207,208] and on silica columns,[209] if a special eluent mixture was used for that macromolecule. They found that under ''critical'' conditions the sorbent did not ''see'' the polymeric nature of the chain. The separation was dependent only on the enthalpic interaction of the sample-sorbent pair (so-called ''critical chromatography'' or ''liquid chromatography at critical conditions''.[210–212]

The LC/CC mode relates to a chromatographic situation where the entropic and enthalpic interactions of the macromolecule and the column packing compensate each other, as shown in Equation (26):

$$\Delta G = \Delta H - T\Delta S = 0 \quad (26)$$

Therefore, we can derive Equation (27):

$$K_d = e^{-\frac{\Delta G}{RT}} = 1 \quad (27)$$

Rewriting this result for retention in elution volume terms, we directly get the experimentally observed result that the chromatographic peak position is independent

of the molar mass of the analyte and equal to the accessible volume of the stationary phase, which is stated in Equation (28):

$$V_e = V_0 + K_d(\text{LC/CC})V_{pore} = V_0 + V_{pore} = V_t \quad (28)$$

The Gibbs free energy of the macromolecule remains constant when it penetrates the pores of the stationary phase ($\Delta G = 0$). The distribution coefficient K_d is unity, regardless of the size of the macromolecules, and all macromolecules of equal chemical structure elute from the chromatographic column in one peak. The term ''chromatographic invisibility'' is used to refer to this phenomenon. This means that the chromatographic behavior is not directed by the size, but by the heterogeneities (chemical structure, branching point, endgroup, etc.) in the macromolecular chains.[207–210]

In general, as the Gibbs free energy is influenced by the length of the polymer chain and its chemical structure, contributions G_i for the polymer chain and G_j for the heterogeneity may be introduced, as stated in Equation (29):

$$\Delta G = \sum n_i \Delta G_i + \sum n_j \Delta G_j \quad (29)$$

For a perfectly uniform homopolymer chain the free energy change is determined by the contribution of the repeating units of the polymer chain (Equation 30):

$$\Delta G = \sum n_i \Delta G_i \quad (30)$$

At the critical point of adsorption of the polymer chain of a complex polymer, however, the contribution G_i becomes zero and chromatographic behavior is exclusively directed by imperfections in the macromolecular chain (Equation 31):

$$\Delta G = \sum n_j \Delta G_j \quad (31)$$

This chromatographic effect can be employed to determine imperfections in the polymer chain selectively and without any contribution by the repeating units themselves. LC/CC has been successfully used for the determination of the FTD of telechelics and macromonomers,[213–217] for the analysis of block copolymers,[218–220] macrocyclic polymers,[221] and polymer blends.[222–224]

Thus, LC/CC represents a chromatographic separation technique yielding fractions which are homogeneous in one property (e.g. chemical composition) but polydisperse in a different property (e.g. molar mass). These fractions can readily be analysed by SEC, which for chemically homogeneous fractions provides true MMDs without interference of CCD or FTD. Therefore, the combination of LC/CC and SEC in a 2-D chromatography experiment can be regarded as ''orthogonal'' chromatography in the strict sense provided that LC/CC is used as the first dimension separation mode. Consequently, for functional homopolymers being distributed in functionality and molar mass, coupling LC/CC with SEC can yield combined information on FTD and MMD. Such property information is important, e.g. for the quality control of amphiphilic polyalkylene oxides.

There is another area where the 2-D combination of LC/CC and SEC is extremely useful and can give results no other technique can provide in a single experiment. The 2-D separation of segmented copolymers (such as block- or graft- or comb-shaped copolymers) allows the complete molecular characterization of the copolymer with regard to individual segment molar masses and composition. It has been demonstrated that with such a set-up the polydispersities of copolymer segments can be determined independently.[225]

The thermodynamics of segmented copolymers is based on the idea that free energy change ΔG_{AB} of a segmented copolymer molecule, A_nB_m, is the sum of the contributions of segments A and segments B, ΔG_A and ΔG_B, respectively, which can be expressed by Equation (32):

$$\Delta G = \sum n_A \Delta G_A + \sum n_B \Delta G_B + \chi_{AB} \quad (32)$$

where χ_{AB} is the Flory–Huggins parameter describing the interactions between segments A and B. It has been demonstrated for a number of block copolymers[27,34] that no specific interactions between the heterosegments A and B ($\chi_{AB} = 0$) can be measured by chromatography. Using this assumption the change in the Gibbs free energy is solely dependent on the energy contributions of segments A and B, as is shown in Equation (33):

$$\Delta G = \sum n_A \Delta G_A + \sum n_B \Delta G_B \quad (33)$$

Applying experimental conditions, which correspond to the critical point of homopolymer A, the A segment in the segmented copolymer will become chromatographically invisible, as expressed in Equation (34):

$$\Delta G_A = 0 \quad (34)$$

Consequently, the retention of the segmented copolymer will be determined solely by the chromatographic properties of segment B. This is shown in Equation (35):

$$\Delta G_{AB} = \sum n_B \Delta G_B \quad (35)$$

This also means that the distributions coefficient for this system, K_d^{AB} can be reduced to the very simple term which is used for homogeneous molecules (Equation 36):

$$K_d^{AB} = K_d^B \quad (36)$$

Repetition of such an experiment using critical conditions for segment B allows the determination of molecular parameters for the other segment A in the copolymer. The same equations derived above apply, just the parameters for segments A and B are exchanged. Critical conditions for segment B mean that Equation (37) holds:

$$\Delta G_B = 0 \tag{37}$$

and the copolymer shows only the chromatographic behavior of segment A (Equation 38):

$$\Delta G_{AB} = \sum n_A \Delta G_A \tag{38}$$

The retention is then given by Equation (39):

$$K_d^{AB} = K_d^A \tag{39}$$

The characterization of ABA triblock copolymers can be done in a similar way to the analysis of diblock copolymers. The two possible cases for this type of investigation are:

(a) analysis with respect to the center block B using the critical conditions of the outer blocks A
(b) the analysis of the terminal A segments using the critical conditions of the center block B.

It is particularly useful to carry out experiments at the critical point of A. The separation occurs then with respect to the chain length of B, yielding fractions which are monodisperse with respect to B and polydisperse with respect to A and A′. These fractions can be analyzed selectively with respect to the outer blocks A and A′ in separate experiments.

4.3.3 Temperature-rising Elution Fractionation

This is not, strictly speaking, a chromatographic technique but it uses the same equipment and leads to detector traces which resemble chromatograms. This method is widely used for the short-chain branching characterization of polyolefins in the petrochemical industry.

Many polyolefins are in fact copolymers; the second comonomer introduces short-chain branches into the macromolecule. The copolymer properties depend strongly on the average composition and its sequence length distribution. In the case of polyethylene copolymers, changes in composition change the ease and temperature at which the polymer chains can crystallize. This property allows for the determination of composition distribution by measuring TREF. The TREF techniques rely on the fact that the redissolution temperature of a precipitated sample depends strongly on the number of short-chain branches. A chromatographic pump will transport the redissolved species through the column loaded with precipitated polymer into a concentration detector, which in turn will measure the concentration of the fraction redissolved at a given temperature, T, as shown in Figure 34.

Figure 34 Schematic layout of a TREF instrument with thermostated TREF column.

4.4 Separation Techniques for the Second Dimension

The LC methods described in section 4.3 can also be used in the subsequent separation stage in a multidimensional chromatography set-up. However, as pointed out earlier (cf. section 4.2), it is advantageous to use gradient LC or LC/CC in the first separation dimension. On the other hand, SEC is preferentially used as the second method to retrieve molar mass information. In theory, TREF can also be used in a later separation step; however, for practical reasons, this is not advisable.

There are a number of chromatographic separation methods which can only be used in the last stage of a multidimensional experiment.

4.4.1 Size-exclusion Chromatography

SEC is described in the section of techniques for the second dimension, because of its primary benefits there (cf. section 4.2.2). However, it can also be used with lower efficiency and more biased results in the first separation dimension. This technique was developed for the separation and characterization of large molecules. It is also called Gel Filtration Chromatography for natural and biopolymers and known as GPC for synthetic polymers.

The principles are the same in both cases and rely on the fact that the macromolecule can only partially penetrate the porous packing, depending on its molecular size (not molar mass). The molecular size of a macromolecule in solution, or more accurately its hydrodynamic volume,

will depend on its chain length, the nature of the repeating units, chemical composition, molecular topology and the thermodynamic quality of the solvent. The same dependencies exist for the distribution coefficient in SEC, which can lead to the co-elution in SEC of species having identical hydrodynamic radius, but different composition, molecular architecture, and so forth. Large molecules can only access pores larger than the hydrodynamic radius of the molecule and will elute from the column early. If macromolecules are larger than the biggest pores, they will be totally excluded from the pore volume and will not be separated into fractions of different molar mass. On the other hand, the smallest molecules might be able to penetrate into all pores in the packing. They also will not be separated and will all co-elute at the total permeation volume. This chromatographic behavior is illustrated in Figure 35.

Similarly to the thermodynamic treatment of LC, retention in SEC can be described by basic thermodynamic entities and can be determined by measuring the concentration of the molecule in the stationary and mobile phases, as expressed in Equation (40):

$$K_d(\text{SEC}) = \frac{a_s}{a_m} = e^{\frac{\Delta S}{R}} \tag{40}$$

In ideal SEC separations the retention in the column is only governed by the entropy loss when the macromolecule enters the pore of the packing. No enthalpic interaction should be present in order to allow for accurate molar mass determinations.

The retention in ideal SEC experiments is given by Equation (41):

$$V_e = V_0 + K_d(\text{SEC})V_{\text{pore}} \tag{41}$$

Figure 35 Size-exclusion behavior of macromolecules of different size on a porous column packing.

This equation looks very similar to Equation (23). The only difference is the magnitude of K_d, which is always less than unity for SEC separations and reaches a maximum value of unity for molecules which enter all pores.

Ideal SEC conditions are difficult to obtain for real macromolecules, however. As in the case of LC, there are contributions from both entropic and enthalpic terms to the distribution coefficient (cf. Equation 25).

In such cases, the retention for molecules with enthalpic interactions is higher and they will elute later from the column. This behavior can be described by Equation (42):

$$V_e = V_0 + [K_d(\text{SEC})K_d(\text{LC})]V_{\text{pore}} \tag{42}$$

In this equation the term $K_d(\text{LC})V_{\text{pore}}$ describes the delayed elution from the column as compared to the ideal case. This equation is mathematically identical to the respective equation for LC. However, the dominant parameter is $K_d(\text{SEC})$ and the entropy change governs the penetration of the analyte into the pores.

4.4.2 Capillary Electrophoresis

CE is a very efficient microseparation method (typically $N > 100\,000$), which uses a strong electric field to create an electro-osmotic flow in which the species will migrate. The reason for that is that the surface of the silicate glass capillary contains negatively-charged functional groups that attract positively-charged counterions. The positively-charged ions migrate towards the negative electrode and carry solvent molecules in the same direction. This overall solvent movement is called electro-osmotic flow. During a separation, uncharged molecules move at the same velocity as the electro-osmotic flow (with very little separation). Positively-charged ions move faster and negatively-charged ions move more slowly.

CE can also be used as a first set in multidimensional separation, but its practical use here is very limited due to the minute sample amounts injected.

For further information and details on the CE technique, please consult the articles in this encyclopedia.

4.4.3 Supercritical Fluid Chromatography

SFC is a relatively recent chromatographic technique which was commercialized in the early 1980s.

In SFC, the sample is carried through a capillary or packed column by a supercritical fluid (typically carbon dioxide). The properties of the mobile phase can be modified easily by polar additives and/or pressure programming, just as in gradient HPLC, to optimize selectivity. All three basic modes of chromatography (interaction, size-exclusion and critical conditions) have been verified in SFC separations.[226] SFC is a very

efficient separation technique, which has most of its applications in low molecular weight separations.

SFC has several advantages over conventional chromatographic techniques. SFC separations can be done considerably faster than HPLC separations, because the diffusion of solutes in supercritical fluids is about 10 times greater than that in liquids (and about 3 times less than in gases). This results in a decrease in resistance to mass transfer in the column and allows for fast high resolution separations. Compared with GC, capillary SFC can provide high resolution chromatography at much lower temperatures. This allows fast analysis of thermolabile and nonvolatile compounds. These advantages make SFC a good choice for multidimensional chromatography set-ups. Since SFC is a mobile phase-destroying technique, it can only be used in the last separation step in multidimensional separations.

4.4.4 Gas Chromatography

As with SFC, GC is a mobile phase-destroying technique and can only be used in the last stage of multidimensional separations. It also shares with SFC the high efficiency and speed of separations. However, it is limited to relatively low molecular weight compounds which are volatile without degradation and thermostable.

Most ''multidimensional'' applications reported in the literature use the first dimension for precleaning and removal of high molar mass species and not for complete characterization of the samples. Examples of such applications are the removal of humic acids from pesticides in soil extracts by SEC/GC and of high molecular byproducts from mono, di, and triglycerides.

For an indepth description of the technique, please refer to the *Gas Chromatography* in this encyclopedia.

4.5 State-of-the-art of On-line Coupled Two-dimensional Chromatography

This section will illustrate the current state and future potential of 2-D chromatography by reviewing separations published in the literature. Examples will be given for different separation techniques and combinations of these.

4.5.1 Two-dimensional Separations by Liquid Chromatography and by Size Exclusion Chromatography

Much work on chromatographic cross-fractionation was carried out with respect to the combination of SEC and gradient HPLC. In early experiments SEC was used as the first separation step, followed by HPLC. In a number of early papers the cross-fractionation of model mixtures was discussed. Investigations of this kind demonstrated the efficiency of gradient HPLC for separation by chemical composition. Mixtures of random copolymers of styrene and acrylonitrile were separated by Glöckner et al.[198] In the first dimension an SEC separation was carried out using THF as the eluent and PS gel as the packing. In total, about 10 fractions were collected and subjected to the second dimension, which was gradient HPLC on a CN bonded-phase using iso-octane/THF as the mobile phase. Model mixtures of random copolymers of styrene and 2-methoxyethyl methacrylate were separated in a similar way, the mobile phase of the HPLC mode being iso-octane/methanol in this case.[227] This procedure was also applied to real-world copolymers.[198] Graft copolymers of methyl methacrylate onto EPDM were analyzed by Augenstein and Stickler;[228] whereas Mori reported on the fractionation of block copolymers of styrene and vinyl acetate.[229] For all these experiments the same limitation with respect to the SEC part holds true: when SEC is used as the first dimension, true MMDs are not obtained.

From the theoretical point of view, a better copolymer separation set-up is prefractionation through HPLC in the first dimension and subsequent analysis of the fractions by SEC. HPLC was found to be rather insensitive towards molar mass effects and yielded very uniform fractions with respect to chemical composition.[230,231]

The major disadvantage of all early investigations on chromatographic cross-fractionation was related to the fact that both separation modes were combined with each other either off-line or in a stop-flow mode. Regardless of the separation order SEC vs HPLC or HPLC vs SEC, in the first separation step fractions were collected, isolated, and then subjected to the second separation step. This procedure, of course, is very time-consuming and the reliability of the results, at least to a certain extent, depends on the skills of the operator.

A fully automated 2-D chromatographic system was developed by Kilz et al.[23,188,194] The operation of the column-switching device is automatically driven by the software, which at the same time organizes the data collection from the detector.

One of the very few applications of 2-D gradient HPLC/SEC was published by Kilz et al. and described the analysis of styrene–butadiene star polymers.[188] Four-arm star polymers based on poly(styrene-*b*-butadiene) were prepared by anionic polymerization to give samples with well-known structure and molar mass control. In a first reaction step, a poly(styrene-*b*-butadiene) with a reactive chain end at the butadiene was prepared. This precursor reacted with a tetrafunctional terminating agent to give a mixture of linear (of molar mass M), 2-arm (2M), 3-arm (3M) and 4-arm (4M) species. Four samples with varying butadiene content (about 20%, 40%, 60%, and

80%) were prepared in this way. A mixture of these samples was used for the 2-D experiment. Accordingly, a complex mixture of 16 components, resulting from the combination of four different butadiene contents and four different molar masses (M, 2M, 3M, 4M) had to be separated with respect to chemical composition and molar mass.

Initially, the 16-component star block copolymer was investigated by SEC. As can be seen in Figure 36, four peaks were obtained. They correspond to the four molar masses of the sample consisting of species with one to four arms. The molar masses are defined by the number of arms and were in the ratio M–2M–3M–4M. Despite the high resolution, the chromatogram did not give any indication of the very complex chemical structure of the sample. Even when pure fractions with different chemical composition were investigated, the retention behavior did not show significant changes as compared to the sample mixture. In each case a tetramodal MMD was visible, indicating the different topological species. The SEC separation alone did not show any difference in chemical composition of the samples, which varied from 20% to 80% butadiene content.

Running the sample mixture in gradient HPLC mode gave poorly resolved peaks, which might suggest different composition, but gave no clear indication of different molar mass and topology, see Figure 37.

Figure 36 SEC chromatograms of the 16-component star block copolymer mixture (A) overlayed with styrene–butadiene 60:40 (B) star copolymer and 20:80 (C); peaks correspond to molar mass separation of different arm numbers.

Figure 37 Gradient HPLC chromatogram of the 16-component star block copolymer mixture; separation is dominated by chemical composition and does not reveal the complexity of the sample.

Figure 38 3-D view of the 16-component star block copolymer mixture; each trace represents an SEC chromatogram from a transfer injection.

The combination of the two methods in the 2-D set-up dramatically increased the resolution of the separation system and gave a clear picture of the complex nature of the 16-component sample. A 3-D representation of the gradient HPLC/SEC separation is given in Figure 38. Each trace represents a fraction transferred from HPLC to SEC and reflects the result

of the SEC analysis in the second dimension. Based on the composition of the sample, a contour map with the coordinates' chemical composition and molar mass is expected to show 16 spots, equivalent to the 16 components. Each spot would represent a component which is defined by a single composition and molar mass. The experimental evidence of the improved resolution in the 2-D analysis is given in Figure 39. This contour plot was calculated from experimental data based on 28 transfer injections.

The contour plot clearly revealed the broad chemical heterogeneity (*y*-axis, chemical composition) and the wide MMD (*x*-axis) of the mixture. The relative concentrations of the components were represented by colors. Sixteen major peaks were resolved with high selectivity. These correspond directly to the components. For example, peak 1 corresponds to the component with the highest butadiene content (80%) and the lowest molar mass (molar mass 1M) whereas peak 13 relates also to a molecule with 80% butadiene content but a molar mass of 4M. Accordingly, peak 16 is due to the component with the lowest butadiene content and a molar mass of 4M, representing a 4-arm star block copolymer with a styrene–butadiene content of 80 : 20.

A certain molar mass dependence of the HPLC separation is indicated by a drift of the peaks for components of similar chemical composition: see peaks 1-5-9-13, for example. This kind of behavior is normal for polymers, because pores in the HPLC stationary phase lead to size-exclusion effects which overlap with the enthalpic interactions at the surface of the stationary phase. Consequently, 2-D separations of this type will in general be not orthogonal but skewed, depending on the pore size distribution of the stationary phase and the nature of the sample. The quantitative amount of butadiene in each peak could be determined via an appropriate calibration with samples of known composition. The molar masses could be calculated based on a conventional molar mass calibration of the second dimension.

The mapping of ethoxylated fatty alcohols and ethylene oxide–propylene oxide block copolymers by 2-D chromatography was discussed by Trathnigg et al.[232] They

Figure 39 Contour plot of the 16-component styrene–butadiene star block copolymer mixture characterized by the 2-D HPLC/SEC separation.

Figure 40 LC chromatogram of an aliphatic polyester sample at critical conditions; peak labels identify endgroups or functionality.

combined LAC and SEC and were able to determine the CCD and the MMD of the polyethers.

4.5.2 Two-dimensional Separations by Liquid Chromatography at Critical Conditions and Size Exclusion Chromatography

The analysis of aliphatic polyesters with respect to FTD and MMD has been demonstrated.[188,233] Polyesters from adipic acid and 1,6-hexanediol are manufactured for a wide field of applications with an output of thousands of tonnes per year. They are intermediates for the manufacture of polyurethanes, and their FTD is a major parameter affecting the quality of the final products. In particular, nonreactive cyclic species are responsible for the ''fogging effect'' in polyurethane foams.

For the separation of the polyesters with respect to functionality, LC/CC was used, the critical point of adsorption of the polymer chain corresponding to an eluent composition of acetone–hexane 51 : 49 (v/v) on silica gel. The critical chromatogram of a polyester sample together with the functionality fraction assignment is given in Figure 40. The ''ether'' peaks could be attributed to the formation of ether structures in the polyester samples by a condensation reaction.

The MMDs of the functionality fractions could be determined by preparatively separating the fractions and subjecting them to SEC. The SEC chromatograms of fractions 1–9 are summarized in Figure 41. For a number of fractions oligomer separations were obtained, which could be used to calibrate the SEC system.

The very complex nature of the sample could be verified in a 2-D experiment using LC/CC as the first dimension to separate for functionality and SEC in the second dimension to determine molar masses. The contour plot in Figure 42 reveals the structural complexity of the sample including the functionality fractions from LC/CC and the oligomer separations from SEC which were well-recognizable. The sample was prepared from an adipic acid-rich reaction mixture resulting in an acid number of about 5. The high content of dicarboxylic acid endgroups is clearly reflected in the contour map. Quantification of

Figure 41 SEC separation of different fractions taken from the LC/CC separation of the aliphatic polyester sample (cf. Figure 40).

the contour plot yielded quantitative information on both FTD and MMD.

The analysis of an octylphenoxy-terminated PEO with respect to FTD and MMD has been demonstrated by Adrian et al.[225] A separation of the sample with respect to the terminal groups could be achieved by LC/CC on an RP-18 stationary phase and a critical eluent composition of methanol–water 86 : 14 (v/v). All peaks in the chromatogram could be identified by MALDI/TOF MS as pure fractions of different functionality, proving that the separation followed the chemical structure of the endgroups. The combination of LC/CC with SEC in a 2-D chromatography experiment resulted in the contour plot shown in Figure 43.[225] At the abscissa, the retention volume of the SEC runs (second dimension) is given, whereas the ordinate gives the retention volume of the LC/CC (first dimension). Relative concentrations are mapped to a color code on a log scale to make small quantities visible.

Figure 42 Contour map of the 2-D LC/CC and SEC separation of the aliphatic polyester with acid number of about 5; functionality (on *y*-axis) was calibrated by model compounds.

The contour plot (cf. Figure 43) clearly reveals five spots corresponding to the five functionality fractions, fraction 2 being the main fraction containing the α-octylphenoxy-w-hydroxy oligomers. In addition, α,w-di(octylphenoxy) oligomer fractions and fractions having butylphenoxy endgroups are identified.

The 2-D experiment yielded separation with respect to functionality and molar mass, and FTD and MMD could be determined quantitatively. For calculating FTD, the relative concentration of each functionality fraction must be determined. These concentrations are equivalent to the volume of each peak in the contour plot. With the appropriate software this can be done easily. Determination of the MMD for each fraction was possible after calibrating chromatograph 2 with PEO calibration standards. Calculation of the MMD could then be achieved in the usual way, taking one chromatogram for each functionality fraction, preferably from the region of the highest peak intensity.

In similar approaches other polyalkylene oxides have been analysed by 2-D chromatography. Murphy et al.[234] separated PEGs and Brij type surfactants according to chemical composition and molar mass by RP HPLC versus SEC.

The analysis of methacryloyl-terminated PEOs by LC/CC versus SEC was described by Krüger et al.[233] The functionality-type separation was conducted on an RP system at a critical eluent composition of ACN–water 43 : 57 (v/v). The functionality fractions, including PEG, α-methoxy-w-hydroxy, α-methoxy-w-methacryloyloxy, and α,w-di(methacryloyloxy) PEO, were identified by MALDI/TOF MS.

Finally, a technical C_{13},C_{15}-alkoxy-terminated PEO was analysed by Pasch and Trathnigg using LC/CC vs SEC.[235]

4.5.3 Two-dimensional Combination of Different High Performance Liquid Chromatography Modes

The deformulation of alcohol ethoxylates, which are an important class of nonionic surfactants, by 2-D chromatography has been published by Murphy et al.[236] This class of products possesses a polydispersity of

Figure 43 2-D separation of octylphenoxy-terminated PEO shown as a contour plot; the labels indicate the molecular structure verified by MALDI/MS.

methylene groups and a distribution of ethylene glycol units in the PEG segment of the nonionic surfactant. The authors established chromatographic methods for both heterogeneities independently and then combined them later for the 2-D investigations. They used an RP system with a 3 µm C-18 column with 100 Å pore width to separate the alcohol alkyl chains using an isocratic mobile phase (methanol–water (95 : 5)) (see Figure 44). The PEG segments were separated on a normal phase system comprising a 3 µm nonmodified silica with 70 Å pores run with a concave water–ACN gradient (see Figure 45). Both chromatograms show high resolution separations for the alcohol groups or the PEG MMD, without *any* indication of any other unresolved property.

The combination of both techniques in a 2-D experiment revealed the complex nature of the surfactant. The authors applied the gradient normal phase liquid chromatography (NPLC) separation of PEG as the first dimension with the reversed phase liquid chromatography (RPLC) as the second dimension using ELSD as a highly sensitive means of detection. Figure 46 shows the 2-D contour map which displays both the alkyl chain separation on the *x*-axis and the ethylene oxide chain length

Figure 44 RP separation of FAE non-ionic surfactant for ethylene oxide content determination.

on the *y*-axis. The separation is not truly orthogonal, which the authors attribute to the concave gradient in the NPLC separation. This separation clearly demonstrates the increased peak capacity of 2-D experiments. The high resolution separation in NPLC showed very high peak capacities of about 15, whereas the RPLC experiment resulted in an extremely good separation into the four

Figure 45 High resolution normal-phase chromatogram of non-ionic surfactant; separation occurs by alkyl chain length without indication of ethylene oxide polydispersity.

Figure 46 2-D contour plot of FAE characterized in an NPLC/RPLC experiment with very high peak capacity (about 70).

alkyl alcohol chains. The total peak capacity in the 2-D experiment is about 70, which agrees very favorably with the theoretical value of about 60 (cf. section 4.1).

The authors were able to distinguish between different samples of one manufacturer and samples of different producers using this technique. They used the polydispersity of the PEG segment and the presence of various C_n chains from the 2-D contour plot as indicators for identifying sample, synthetic process and manufacturer.

Figure 47 Surface plot of the 2-D TREF/SEC characterization of the ethylene–butene copolymer (Ziegler–Natta catalyst). The temperature axis reflects short-chain branching, the molar mass axis shows the broad MMD of the sample.

4.5.4 Temperature-rising Elution Fractionation–Size Exclusion Chromatography Two-dimensional Separations

This method combination has high potential for the study of the physical properties of polyolefins and can relate them to their molecular structure. The thermal properties and the performance of many polyolefin applications depend on the formation of crystalline domains, which are controlled by the type and the degree of branching of the macromolecule.

TREF (section 4.3.3) is a technique which is widely used for the short-chain branching investigation of polyolefins. Micklitz et al. reported on the 2-D characterization of poly(ethylene-co-butene) using different initiator systems.[237]

The 2-D system comprised a preparative TREF unit running in xylene from which samples were collected and manually transfered into a high-temperature SEC system running in 1,2,4-trichlorobenzene at 135 °C. Figure 47 shows the surface plot of the TREF/SEC characterization of the ethylene–butene copolymer, which has been synthesized from a traditional Ziegler–Natta type catalyst. Both the branching distribution (indicated by the measured property elution temperature by TREF) and the MMD (by SEC calibration) are very broad, as would be expected from a Ziegler–Natta type catalyst. The average molar mass of the sample was about 100 000 g mol^{-1}.

Figure 48 shows an ethylene–butene copolymer formed from a metallocene catalyst using otherwise identical conditions (comonomer ratio, molar mass). Metallocene catalysts marked a new step in polyolefin synthesis, because they allow a much improved control of the structure of the growing macromolecule. The high degree of structure and molar mass control with a metallocene catalyst can be seen from this figure. The width of the 3-D peak with respect to the elution temperature and the molar mass axis is much smaller than that of the Ziegler–Natta product. This indicates that the degree of branching and the insertion of new monomers into the growing polymeric chain can indeed be controlled in a way not possible before.

4.6 Conclusions and Future Developments

Multidimensional chromatography separations are currently one of the most promising and powerful methods for the fractionation and characterization of complex

Figure 48 3-D surface plot from a TREF/SEC experiment of a ethylene–butene copolymer formed by a metallocene catalyst (refer to Figure 47 for details).

sample mixtures in different property coordinates. It combines extraordinary resolution and peak capacity with flexibility and overcomes the limitations of any given single chromatographic method. This is the basis for the identification and quantification of major compounds and byproducts, which might adversely affect product properties if not detected in time.

Using a chromatographic separation which is selective towards functionality or chemical composition in the first dimension and SEC in the second dimension, truly ''orthogonal'' separation schemes can be established. Thus, the combination of gradient HPLC versus SEC yields quantitative information on CCD and MMD, while coupling LC/CC and SEC is useful for the analysis of functional homopolymers and block copolymers in the coordinates FTD/MMD and CCD/MMD respectively. Even more complex systems, such as graft copolymers and polymer blends, in which each component may be chemically heterogeneous itself, can be analyzed.

Although 2-D LC is experimentally more demanding than other chromatographic techniques, the complete characterization yields much more qualitative and quantitative information about the sample, and results are presented in an impressively simple way. The contour plot of a 2-D separation maps all obtainable information and allows a fast and reliable comparison between two samples. For future development, the automated comparison of the results of different samples can be considered as an important step to improve process control and quality management. Currently, there is much activity to identify the best method combinations for multidimensional chromatography of many applications which are difficult to separate and quantify.

Recent improvements in the efficiency of the interactive chromatography of macromolecules and other separation modes (e.g. SEC, CE) widen the applicability of 2-D analyses. The next step is the on-line identification of fractions using information-rich detection systems such as FTIR and MS described in section 3 of this article. This will advance the state of the art to a still higher level.

LIST OF SYMBOLS

a_m	activity (concentration) in mobile phase
a_s	activity (concentration) in stationary phase
c	concentration
f	response factor
G	Gibbs free energy
K^*	optical constant in light scattering
K_d	distribution coefficient
M	molar mass
M_w	weight-average molar mass
m_i	mass of species i
n_i	peak capacity of the i-th dimension
N	number of theoretical plates
$P(\Theta)$	scattered light angular dependence
R	universal gas constant
$R(\Theta)$	intensity of scattered light at the angle Θ
V_0	exclusion volume
V_e	elution volume
V_h	hydrodynamic volume
V_p	volume at peak maximum
V_{pore}	pore volume
V_t	total penetration volume
w	weight fraction
η	viscosity of a solution
λ	wavelength
ϑ	projection angle between two separation methods
i	portion of copolymers eluted
V	volume
x	area of slice
j	detector
M_C	molar mass of copolymers
A_2	second virial coefficient
N_A	Avogadro's constant
$[\eta]$	intrinsic viscosity
χ_{AB}	Flory–Huggins parameter
R_g	radius of gyration
η_0	viscosity of a solvent (viscosity of the pure mobile phase)
η_{sp}	specific viscosity
P	pressure
a	Mark–Houwink exponent
M_n	number-average molar mass
K	constant factor in the Mark–Houwink equation
η_{rel}	relative viscosity
H	interaction enthalpy
T	absolute temperature
d_p	diameter of column packing
f	dilution factor
M_v	viscosity-average molar mass
n_i	number of species i
S	entropy
V_{inj}	injection volume

ABBREVIATIONS AND ACRONYMS

ACN	Acetonitrile
CCD	Chemical Composition Distribution
CE	Capillary Electrophoresis
EA	Ethyl Acrylate
ELSD	Evaporative Light Scattering Detection
EPDM	Ethylene–Propylene–Diene Rubber
ESI	Electrospray Ionization

FAE	Fatty Alcohol Ethoxylate
FFF	Field-flow Fractionation
FTD	Functionality Type Distribution
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
GC/MS	Gas Chromatography/Mass Spectrometry
GPC	Gel Permeation Chromatography
GTP	Group Transfer Polymerization
HPLC	High-performance Liquid Chromatography
IR	Infrared
LAC	Liquid Adsorption Chromatography
LALLS	Low Angle Laser Light Scattering
LC	Liquid Chromatography
LC/CC	Liquid Chromatography at the Critical Point of Adsorption
LS	Light Scattering
MAD	Molecular Architecture Distribution
MALDI	Matrix-assisted Laser Desorption/Ionization
MALLS	Multiangle Laser Light Scattering
MMD	Molar Mass Distribution
MS	Mass Spectrometry
NMR	Nuclear Magnetic Resonance
NPLC	Normal Phase Liquid Chromatography
PDMS	Polydimethyl Siloxane
PEG	Polyethylene Glycol
PEO	Polyethylene Oxide
PMMA	Polymethyl Methacrylate
PnBMA	Poly-n-butyl Methacrylate
PPG	Poly(propylene glycol)
PS	Polystyrene
RI	Refractive Index
RP	Reversed Phase
RPLC	Reversed Phase Liquid Chromatography
SAN	Styrene–acrylonitrile
SEC	Size Exclusion Chromatography
SFC	Supercritical Fluid Chromatography
S/N	Signal-to-noise
THF	Tetrahydrofuran
TLC	Thin-layer Chromatography
TOF	Time-of-flight
TREF	Temperature-rising Elution Fractionation
UV	Ultraviolet
VIS	Visible
VISC	On-line Viscometry
2-D	Two-dimensional
3-D	Three-dimensional

Dielectric spectroscopy is the measurement of complex permittivity (or ''dielectric constant'') as a function of frequency. This measurement can also be done as a function of temperature or time at fixed frequencies to determine various physical and chemical properties of a given polymer. The permittivity is usually measured by placing the sample in contact with electrodes and applying a sinusoidal voltage. Permanent and induced dipoles, and also ion or electron conduction, all contribute to the dielectric response of a material. Dielectric spectroscopy can be used to probe molecular relaxation processes in polymers such as the glass transition or phase transitions such as a melt. For many of the relaxations, it is among the most sensitive of the thermal analysis techniques. Dielectric spectroscopy can also be used to follow chemical changes in polymer systems, such as polymer cure or aging. Because of its enormous frequency range (10^{-6}–10^{12} Hz), dielectric spectroscopy can follow a wide variety of phenomena. However, since it requires either dipole rotation or charge transport, there are some molecular processes that may not be dielectrically active. In addition, analysis of the measured data can be difficult when there are different phenomena occurring simultaneously.

1 INTRODUCTION

The study of dielectric properties in materials can be said to extend back over a 100 years. Some of the earliest measurements were made by Drude,[1] who, among other things, studied dielectric dispersion behavior of materials at optical frequencies. One of the first and best known works to relate experimental dielectric response to molecular phenomena was published by Debye,[2] who won the 1936 Nobel Prize in Chemistry for his work. Debye's text, along with texts such as those written by Smyth,[3] Smith,[4] Fröhlich,[5] and Böttcher et al.,[6,7] dealt primarily with dielectric behavior of small molecules. Considerable effort on the dielectric behavior of macromolecules was not expended until the 1950s and 1960s. Much of this effort was reviewed in the landmark texts by Von Hippel[8,9] and McCrum et al.[10] These texts are still required references for investigators of dielectric properties of polymers. Other more recent texts that specialize in the dielectric characterization of polymers include Hedvig,[11] Riande and Saiz,[12] Runt and Fitzgerald,[13] and Havriliak and Havriliak.[14]

Dielectric spectroscopy is now a well-established method not only for studying electronic properties, but also for providing fundamental understanding of molecular dynamics processes in polymers. In this respect, dielectric spectroscopy is analogous to dynamic mechanical analysis (DMA). However, instead of the mechanical oscillation employed by DMA, an electrical oscillation is applied to the sample. One of the primary advantages of dielectric spectroscopy over DMA and other techniques, is the extreme breadth of the frequency range (from $\sim 10^{-6}$ to $\sim 10^{12}$ Hz). Of course, a number of different experimental techniques are required in order to span this entire range. However, the 18 decades of timescale available allow for a wide variety of molecular processes to be probed. Dielectric analysis is one of the few analytical techniques that can follow transformations from low-viscosity liquids to rubbery solids to hard glassy solids. It can provide information such as mixture miscibility, onset of flow, molecular relaxations, thermal transitions, and polymerization reaction rates. Finally, dielectric measurements can be considerably more sensitive to changes in material properties than other thermal analysis techniques.

This article is concerned with dielectric spectroscopy applied to polymeric systems. It is not possible to include all the theoretical and experimental aspects, so only a broad overview is given. The interested reader may refer to the texts listed above or to the broad base of literature for more detailed information. The next section discusses various aspects of experimental instrumentation, including limitations and pitfalls. The following section covers data analysis and provides definitions and techniques that are commonly used in the dielectric community. The final section gives some examples of measurement applications for which dielectric spectroscopy is particularly effective.

2 INSTRUMENTATION AND SAMPLE PREPARATION

2.1 Instrument Basics

In dielectric spectroscopy, a sample is placed in contact with two or more electrodes and a time-varying voltage is applied across the electrodes. In most cases, these voltages and currents are converted into electrical impedances and the impedances are then related to sample permittivity by incorporating information about the electrode geometry. Because of the extreme frequency range over which dielectric measurements can be made, there is no single instrument that covers the entire range. Table 1 lists some of the more common types of dielectric instruments along with their typical frequency coverage.

In time-domain spectrometry, a voltage step is applied to the sample, and its response is measured as a function of time. Thus it is analogous to stress–relaxation measurements in mechanical analysis. Conversion to frequency domain data is accomplished via a Fourier transform. While the time-domain technique can extend to microwave frequencies, it is most accurate at very low frequencies (sub-hertz to tens of hertz). Unlike the step-function waveform used in time-domain spectrometry, the other measurement techniques listed in Table 1 use sinusoidal voltages to perturb the sample. These other techniques are therefore inherently frequency domain measurements. The impedance analysis technique can be sub-categorized into two primary methods: frequency response analyzers and impedance bridges. Frequency response analyzers use two phase-sensitive voltmeters to measure the voltage and current response of the sample. Impedance bridges use an adjustable compensation impedance to balance the impedance of the sample. Impedance analyzers are the most commonly used instruments for measurements on polymers. They provide reasonable accuracy in the frequency range where most polymer relaxations occur. Additional information on these techniques can be found in reviews by Kremer and Arndt[15] and Pochan et al.[16]

Table 1 Summary of the various types of dielectric measurement techniques

Time-domain spectrometer	$\sim 10^{-6}$–10^{10} Hz
Impedance analysis	$\sim 10^{-4}$–10^{7} Hz
Reflectometry	$\sim 10^{6}$–10^{9} Hz
Network analysis	$\sim 10^{7}$–10^{12} Hz

When accurate measurements are required at frequencies above 10 MHz, reflectometry and network analysis techniques are most appropriate. In reflectometry, the sample electrodes and the line connecting the electrodes to the instrument become important parts of the circuit and must be configured with great precision. The reflectometer uses microwave techniques to measure the reflection coefficient from the sample. Network analysis techniques also use microwave techniques to measure sample permittivity. However, instead of placing samples between electrodes, samples are placed in waveguides (e.g. rectangular or coaxial) or held in free space and their network scattering coefficients are measured. A numerical inversion algorithm must then be employed to calculate the permittivity from the scattering coefficients.[17]

2.2 Measured Parameters

Other than the very high-frequency microwave techniques, dielectric spectroscopy usually involves a sample that is in close proximity to a pair of electrodes. When a voltage is applied across the electrodes, an electric field exists within the sample and it becomes polarized in response to that field. The dielectric apparatus then measures the current generated by the sample. When the applied voltage is sinusoidal, the response current from the sample is also sinusoidal. Figure 1 illustrates such a voltage and current response for a hypothetical polymer sample. It shows that the measured current is the same frequency as the applied voltage, but it is shifted along the time axis. The quantities that relate the current response to dielectric material quantities are the phase shift, δ, and the relative change in amplitude. The real part of the waveforms for the voltage and current can be expressed by Equations (1) and (2):

$$\mathrm{Re}[V(t)] = V_0 \cos(wt) \tag{1}$$

$$\mathrm{Re}[I(t)] = I_0 \cos(wt + \delta) \tag{2}$$

where $V(t)$ and $I(t)$ are the voltage and current as a function of time, V_0 and I_0 are the amplitudes of $V(t)$ and

Figure 1 Voltage and current response of a hypothetical polymer material.

$I(t)$, and w is the angular frequency of the sinusoidal waveform. More generally, voltage and current are complex quantities, which are better expressed in terms of impedance (the ratio of voltage to current). In particular, the sample within the electrodes can be represented as a simple circuit element with a characteristic impedance, Z. Again, because the response is measured at a non-zero frequency, the impedance has both a real term and an imaginary term (Equation 3):

$$Z = \frac{V}{I} = Z' + iZ'' \tag{3}$$

where the prime indicates the real part and the double prime indicates the imaginary part. By incorporation of information about the electrode geometry, the impedance values can be converted to permittivities. A detailed description of the conversion of impedance to permittivity is provided in the next section, which covers specific electrode geometries.

Because an impedance bridge must use a specific circuit to balance the unknown impedance of the sample, polymers are usually modeled as being electrically equivalent to a resistor and capacitor connected in parallel to each other. This is shown in Figure 2. Other more complicated circuits have also been used to model dielectric behavior,[18] but the circuit shown in Figure 2 is appropriate for most polymer samples. It should be noted that a sample may also be modeled as a capacitor and resistor in series, and there is a mathematical equivalence between this series circuit and the parallel circuit of Figure 2.[10] Using elementary circuit analysis, the capacitance, C, and resistance, R, of Figure 2 are related to the complex impedance by Equation (4):

$$\frac{1}{Z} = \frac{1}{R} - iwC \tag{4}$$

Figure 2 Parallel resistor and capacitor circuit used to model impedance of polymers and the complex impedance diagram that characterizes this circuit.

Suitable rearrangement of Equation (4) along with Equation (3) provides Equations (5) and (6):

$$Z' = \frac{R}{1 + w^2R^2C^2} \tag{5}$$

$$Z'' = \frac{wR^2C}{1 + w^2R^2C^2} \tag{6}$$

Combining Equations (5) and (6) give the following useful result (Equation 7):

$$\left(Z' - \frac{R}{2}\right)^2 + (Z'')^2 = \frac{R^2}{4} \tag{7}$$

which is the equation of a circle of radius $R/2$ and centered at $Z' = R/2$ and $Z'' = 0$. The upper half of this circle (corresponding to $Z'' > 0$) is shown in Figure 2. The semicircle in Figure 2 assumes that C and R are constant as a function of frequency. It turns out that real data have more of a distribution of C and R values which result in semicircles that are skewed and that have centers somewhat below the Z'-axis. As will be shown later, complex impedance plots such as that shown in Figure 2 are useful for providing insight into the processes that contribute to a particular sample's dielectric behavior. They are also useful for situations where complicated electrode geometries must be used so that quantitative calculation of permittivity is not practical.

2.3 Electrode–Sample Configurations

By far the most commonly used electrode geometry is the parallel-plate arrangement. Two planar electrodes are used to sandwich a thin, flat sample, as shown in

Figure 3. The parallel-plate geometry is popular because of the simplicity with which dielectric permittivity can be calculated. Using the area of the electrodes, A, and the spacing between them, d, the permittivity is a simple function of the measured impedance. The equations relating impedance to permittivity are summarized in the data analysis section.

Because of the finite size of the electrode, there can be an adverse effect on the measured impedance caused by fringe fields along the perimeter of electrodes. Designing the electrode spacing to be much smaller than the horizontal dimensions can minimize this. Incorporating a guard ring into one of the electrodes can also minimize it. A typical guard ring configuration is shown in Figure 3. As Von Hippel pointed out,[9] the most effective guard electrode has a width at least twice the thickness of the specimen and the unguarded electrode must extend to the outer edge of the guard. Even with a guarded electrode, it is still best to calibrate the electrode area by first measuring the capacitance in air or vacuum (i.e. without the sample). However, this is not always practical.

When calculating permittivity from unguarded parallel-plate electrode measurements, analytical corrections can be applied to the data. These corrections are described in detail in ASTM D 150.[19] To insure quantitative measurements, the samples should be flat and make good contact with the electrodes. In particular, if there is an air gap between the electrode and the sample, the effective capacitance decreases causing a shift in the calculated permittivity. The electrodes can be constructed of metal and placed in contact with the sample, or they may be evaporated, sputtered, or painted directly onto the sample. There are a number of ASTM standards that provide additional guidance for electrode construction and application.[19–21]

An electrode geometry that is similar to the parallel plate is the concentric cylinder configuration, pictured in Figure 4. These electrodes are useful for measuring liquids such as low molecular weight monomers, polymer emulsions, or polymers dissolved in solvents. As for the parallel-plate electrodes, calibration can be done by measuring the empty cell. Alternatively, calibration can be accomplished by measuring the cell filled with a nonpolar liquid with a known dielectric constant. For liquids, it is also common to use a four-probe arrangement where the electrodes are arranged with two outer electrodes inducing the sinusoidal voltage and two inner electrodes measuring the response. This four-probe electrode is useful when ionic mobility is high enough to cause anomalous polarization effects. These effects, also called electrode-blocking effects, are discussed in more detail in subsequent sections.

A third type of electrode that is useful for measuring polymer systems is the interdigitated comb electrode. This type of electrode was first introduced by Armstrong[22] and greatly refined by Senturia et al.[23,24] and Kranbuehl.[25] A simple schematic diagram of such an electrode is shown in Figure 5. Unlike the parallel-plate electrodes, the geometry of comb electrodes is fairly complicated. In addition, there are large fringe fields that exist in the substrate of the electrodes. Hence numerical methods are required for the quantitative calculation of dielectric permittivity.[26] Their primary advantage is that they can be mounted noninvasively on the surface

Figure 3 Parallel-plate electrodes. Also shown is a guard ring used to minimize fringe field effects.

Figure 4 Cylindrical electrodes.

Figure 5 Interdigitated comb electrodes.

of a structure, or can be easily incorporated into laminated structures such as fiber-reinforced composites or adhesive joints.[27] Often valuable information such as molecular relaxation or changes in material properties can be monitored with just the raw impedance data, so that quantitative calculation of permittivity is not necessary.

2.4 Potential Pitfalls

An important aspect of the experimental measurement of materials is the separation of instrument effects from real material behavior. Unfortunately, the scientific literature is full of conclusions that incorrectly attribute instrumental artifacts to the material being measured. Often experimental details, important for correct interpretation of the data, were overlooked during the original research. This section briefly lists the assumptions and instrument effects that can be important when making dielectric measurements.

When making measurements on a sample, two fundamental assumptions are usually made. The first is that the measurement is linear. In other words, the measured impedance is independent of applied voltage. For most conditions, this assumption is true. However, it is possible for dielectrics to experience breakdown at high enough voltages ($>10^6\,\mathrm{V\,cm^{-1}}$). In addition, the measured behavior becomes nonlinear when there are electrochemical reactions resulting from the applied voltage. Again, this is usually restricted to high voltages, and generally does not occur in most polymers systems of interest. The second assumption made when interpreting dielectric data is that the measured property is time invariant. Because the measurement is usually done to follow changes in sample properties as a function of time or temperature, time invariance is not strictly followed. Hence the question of time invariance becomes one of whether the sample is constant within the time it takes to measure the impedance at a given frequency. Typically, most instruments average over several cycles. Hence, the time for a given measurement will take several times the inverse of the frequency. For high frequencies, this measurement time is still less than a fraction of a second. However, for frequencies below 1 Hz, this time can become significant. This is important in experiments such as measurement of changes during chemical reactions.

Another important effect that can occur in ionically conductive polymers is the blocking of ions by the electrodes. Blocking electrode effects can obscure the bulk properties of the sample. This blocking effect is caused by the pile-up of the sample's mobile ions at the electrode/sample interfaces and is especially prevalent in samples where ion mobility is high (e.g. low molecular weight samples or samples at high temperature).[28,29] As the ions accumulate at the electrodes, the sample becomes polarized, so that a large false contribution to the dielectric constant is measured. Besides the sample itself, two major experimental factors may be varied to control the electrode polarization. The first factor is the timescale. As the length of time for the experimental measurement is increased, the ions have more time to accumulate at the electrodes. Thus the blocking effect is minimized by taking data at higher frequencies (shorter timescales). The specific frequency at which blocking becomes important depends on the concentration of ions and the sample viscosity. The second factor that influences electrode polarization is the sample geometry. As the electrode separation decreases, the amount of ions that pile up in a given amount of time increases. Hence increasing the spacing between electrodes can be used to minimize blocking effects. However, increasing the distance between electrodes can have other adverse effects, such as decreased sensitivity and increased fringe fields. Thus optimization of the electrode spacing is often an exercise in compromise, which depends on the sample properties.

Because blocking effects can cause large "false" contributions to the measured data, it is important to be able to detect when this blocking occurs. In order to account for the pileup of ions at the electrodes, the parallel resistor and capacitor model of Figure 2 must be modified. Although more complicated models of blocking effects exist,[18] the simplest model is made by adding a second capacitance in series with the original circuit, as pictured in Figure 6. For this model, the complex impedance is then given by Equations (8a) and (8b):

$$Z' = \frac{R_{\mathrm{bulk}}}{1 + w^2 R_{\mathrm{bulk}}^2 C_{\mathrm{bulk}}^2} \tag{8a}$$

$$Z'' = \frac{w R_{\mathrm{bulk}}^2 C_{\mathrm{bulk}}}{1 + w^2 R_{\mathrm{bulk}}^2 C_{\mathrm{bulk}}^2} + \frac{1}{w C_{\mathrm{blocking}}} \tag{8b}$$

where the subscript bulk indicates material-dependent properties and the subscript blocking indicates the anomalous blocking effects. As in the nonblocking case, Equations (8a) and (8b) can be plotted on a complex

Figure 6 Circuit used to model impedance of polymers that include ion-blocking effects at the electrodes. Also shown is the complex impedance diagram that characterizes this circuit. The ''tail'' is indicative of data that is dominated by the electrode blocking effects.

Figure 7 Complex impedance of a polymer latex emulsion that demonstrates the qualitative validity of the circuit model illustrated in Figure 6 for diagnosing ionic blocking problems.

impedance plot and this is also shown in Figure 6. Again, there is a semicircle that represents the impedance of the material being tested, but also, there is a vertical line that is caused by the ions blocking the electrode. R_0 is the resistance of the sample in the limit of zero frequency. Pictured in Figure 7 for comparison are some actual data from a polymer latex emulsion. These data show the usefulness of the model in diagnosing the presence of electrode blocking effects.

The blocking effect is very much geometry dependent, so interpreting electrode-blocked data is difficult if not useless. Because it has to do with how fast the ions can accumulate at the electrode, it is also time (or frequency) dependent. In Figure 7, each data point corresponds to a different measurement frequency. In these data, there are electrode blocking effects at the lower frequencies where the ions have more time to accumulate. However, at higher frequencies, electrode blocking is no longer a problem, and the data are a valid measure of the material characteristics.

One final difficulty that can adversely affect measurement accuracy is the existence of parasitic impedances. Even the most carefully designed electrode fixture will have finite impedances that result from the wires and electrodes that connect the sample to the measurement instrument. These impedances can become important at frequencies above a few hundred kilohertz. Figure 8 shows a schematic diagram of the undesired impedances that can occur. Jonscher[30] has noted that in conductive samples, parasitic inductances in the electrodes can lead to inaccuracies that become worse as the frequency is increased. Schultz[31] has shown that high frequency anomalies can occur from both inductances and resistances that are present in the sample fixtures.

2.5 Thermally Stimulated Current

One final instrumentation topic that should be mentioned is the subject of thermally stimulated current (TSC) spectroscopy. This technique is different than traditional dielectric spectroscopy in that it is a dc (zero-frequency) technique. A polymer sample is placed between two electrodes and a dc voltage is applied in order to polarize the polymer. It is then cooled and the external field is removed. Then, as the temperature is slowly ramped up again, the depolarization current is measured across the same electrodes. This current corresponds to dipole relaxation. There are also variations of this procedure, but the main concept is that the measured current is a probe of the dipole relaxation. For example, if a polymer glass transition is to be measured, the voltage would be applied at a temperature above the glass transition, then, by cooling the sample into the glassy state, the dipole polarization is locked in. As the polymer is heated back through the transition, the dipoles slowly lose their orientation causing a small but measurable current.

Figure 8 Circuit diagram showing R, L, and C circuit elements from both the sample and electrode/leads that contribute to the overall response.

An advantage of this technique over traditional dielectric spectroscopy is that the dc conditions provide better separation of multiple relaxation peaks. The disadvantage is that the theory and data analysis can be considerably more cumbersome. Comprehensive reviews of TSC spectroscopy have been given by Lavergne and Lacabanne[32] and Ibar et al.[33]

3 DATA ANALYSIS

3.1 Calculated Parameters

Dielectric spectroscopy measures the effect of microscopic phenomena on macroscopic properties. For a material such as a polymer, an applied electric field induces an electric polarization of the material. Usually the magnitude of this polarization is linearly proportional to the applied field. The proportionality constant in this case is called the permittivity and is designated by the symbol ε. A fundamental constant of nature is the permittivity of a vacuum, $\varepsilon_0 = 8.854 \times 10^{-12}\,\mathrm{J^{-1}\,C^2\,m^{-1}}$. Usually the permittivity is expressed as the relative permittivity, which is the ratio of the material permittivity to the permittivity of a vacuum (Equation 9):

$$\varepsilon_r = \frac{\varepsilon}{\varepsilon_0} \tag{9}$$

This can often be a source of confusion since it is common to drop the subscript r from the symbol for relative permittivity. It is usually up to the reader to infer whether ε means permittivity or relative permittivity based on its context. To add to the confusion, the relative permittivity is sometimes also called the ''permittivity'' or the ''dielectric constant''.

In a time-varying or oscillating electric field, the permittivity is best represented by a complex number (Equation 10):

$$\varepsilon = \varepsilon' - i\varepsilon'' \tag{10}$$

In this notation, ε' is the real part of the permittivity, and is often called ''permittivity'' for short; ε'' is the imaginary part of the permittivity, and is usually called the ''dielectric loss factor''. The loss factor is usually associated with energy absorption by the polymer.

Another quantity that is associated with the energy absorption by the sample is the ''loss tangent'' (Equation 11):

$$\tan\delta = \frac{\varepsilon''}{\varepsilon'} \tag{11}$$

This loss tangent is a convenient quantity for qualitative comparison to dynamic mechanical data since it is directly analogous to the mechanical loss tangent. It is also directly calculable from the measured impedance data without knowing the geometrical dimensions of the electrodes. Often it is desirable to compare the permittivity to dynamic mechanical modulus data. However, since it is not directly analogous, a dielectric modulus, M, is usually defined (Equation 12):

$$M = \frac{1}{\varepsilon} \tag{12}$$

Like permittivity, Equation (12) can be separated into real and imaginary dielectric moduli (M' and M'', respectively). In the case where conduction processes are occurring, it is possible to calculate an ''apparent conductivity'' also. This quantity is usually calculated from the dielectric loss factor (Equation 13):

$$\sigma = w\varepsilon'' = w\varepsilon_0\varepsilon_r'' \tag{13}$$

where w is the angular frequency ($w = 2\pi f$).

In order to calculate the quantities defined in Equations (10–12), information about the electrode geometry must be incorporated. Table 2 lists the applicable equations for both parallel-plate electrodes and cylindrical electrodes.

3.2 Origins of Dielectric Properties in Polymers

When analyzing dielectric data, there are two physical phenomena that contribute to the values of complex permittivity: dipole reorientation and conduction. In simple terms, dipoles are manifested by charge asymmetries that exist in molecules or molecular fragments. A molecular fragment that has at least two different atoms can have

Table 2 Calculation of permittivity and loss tangent from measured impedance data

Electrode	Parameter	Equation[a]
Parallel-plate electrode	Dielectric permittivity	$\varepsilon_r' = \dfrac{d}{2\pi f\varepsilon_0\lvert Z\rvert^2 A}Z''$
	Dielectric loss factor	$\varepsilon_r'' = \dfrac{d}{2\pi f\varepsilon_0\lvert Z\rvert^2 A}Z'$
	Loss tangent	$\tan\delta = \dfrac{\varepsilon_r''}{\varepsilon_r'} = \dfrac{Z'}{Z''}$
Concentric cylinder electrode	Dielectric permittivity	$\varepsilon_r' = \dfrac{\ln(b/a)}{4\pi^2 f\varepsilon_0\lvert Z\rvert^2 l}Z''$
	Dielectric loss factor	$\varepsilon_r'' = \dfrac{\ln(b/a)}{4\pi^2 f\varepsilon_0\lvert Z\rvert^2 l}Z'$
	Loss tangent	$\tan\delta = \dfrac{\varepsilon_r''}{\varepsilon_r'} = \dfrac{Z'}{Z''}$

[a] A = area of smallest electrode; d = distance between electrodes; l = length; a = inner electrode radius; b = outer electrode radius.

Figure 9 A portion of a hypothetical polymer chain with molecular fragments that have dipole moments.

an intrinsic dipole moment because different atoms have different affinities for electric charge.[12] Example dipoles are illustrated in Figure 9, which shows a hypothetical polymer fragment. Indicated by arrows are the dipole moments, which are vectors that describe the charge distribution in units of [charge × displacement]. Polymer chains are usually made up of thousands of bonds that can rotate in response to external stimuli. Thus in an externally applied electric field, the dipole fragments will realign themselves to partially cancel the effects of the electric field. This is shown schematically in Figure 10(a). The time that it takes for the dipole to realign itself varies according to the properties of the polymer and external conditions such as temperature and pressure. Thus a polymer can be characterized by measuring the relaxation time (or more precisely the distribution of relaxation times) of the intrinsic dipoles. While Figure 10(a) shows an idealized diagram of dipole orientation, in reality steric hindrances prevent dipoles from fully reorienting in response to an external field. This is especially true in semicrystalline and glassy amorphous polymers where the polymer chains are much more rigidly fixed so that dipoles reorient only very slightly, resulting in a lower dielectric constant and loss factor. Conversely, polymers in a rubbery amorphous or viscous flow state have higher dipole mobility and therefore higher dielectric constants and loss factors.

While Figure 9 shows an example of a polymer with permanent dipoles, it is also possible to induce dipoles in polymers that do not have intrinsic permanent dipole moments. In essence, an applied electric field causes the electron cloud to shift relative to the nuclei, thus creating a spatial charge imbalance. Similar to the behavior of permanent dipole moments, this ability of an external field to ''polarize'' the molecular structure is dependent on the chemical properties of the polymer and its environment.

The second way in which a material responds to an electric field, conduction, involves the physical translation of charged species. Charged species can be either ions or electrons. When an electric field is applied, opposites attract, so a positively charged species will be attracted to the negative electrode, while the negatively charged species will be attracted to the positive electrode. More precisely, the applied electric field perturbs the

Figure 10 Effect of external electric field on (a) dipole moments and (b) charged species.

Brownian motion of the ions so that they tend to drift towards oppositely charged electrodes. This is illustrated in Figure 10(b). While there has recently been considerable development of electrically conductive polymers, most conduction phenomena in polymers are caused by the presence of ions. Often, ions are simply unwanted impurities in the sample. Since they make up such a low percentage of the material, they are often neglected. However, if a polymer has no intrinsic dipole moments, then the dielectric response can often be dominated by these ion impurities. Starkweather et al. have pointed out that not realizing the importance of ion conduction in these types of systems has led to the occasional misinterpretation of polymer dielectric response, particularly in fluoropolymers.[34]

Similarly to dipole reorientation, ion (and also electron) conduction is also affected by various chemical and environmental variables. As the charged species travel towards an electrode, they are slowed by their surroundings. The slower the ions travel, the more *resistant* the material; the faster the ions travel, the more *conductive* the material. Unfortunately, dielectric spectroscopy measures the cumulative response of both dipole

reorientation and conduction. Sometimes the effects of the two phenomena overlap so that one cannot be distinguished from the other.

3.3 Relaxation

One of the primary functions of dielectric spectroscopy is to characterize relaxation phenomena in polymers. In many polymers there are a number of different relaxations that are detectable by dielectric spectroscopy. In amorphous polymers, the main transition is the glass transition and it is usually labeled as the ''α-transition''. Additional relaxations can often be detected at lower temperatures/higher frequencies and these may be labeled β, γ, and δ, in order of progression. Although there is still considerable debate as to the exact nature of the glass transition, it is generally attributed to cooperative motions of polymer molecules.[35] Conversely, sub-T_g relaxations are usually attributed to specific local motions of molecular segments. In semicrystalline polymers, there is still an amorphous phase, so there are still glass and sub-glass relaxations analogous to wholly amorphous polymers. In addition, there is a high-temperature process that is related to the crystalline phase.

Relaxations are manifested by transitions in the polymer properties (e.g. glass to rubber), so they play an important role in the usefulness of a polymer for a given application. Relaxations are typically temperature dependent. However, as in the case of the glass transition, they can also be time or frequency dependent. Hence it is possible to analyze dielectric relaxation data with respect to either temperature or frequency. In terms of temperature, the glass transition is adequately fitted by the well-known Williams–Landel–Ferry (WLF) equation[10,36] (Equation 14):

$$\log \frac{f(T)}{f(T_g)} = \frac{-C_1(T - T_g)}{C_2 + (T - T_g)} \tag{14}$$

where $f(T)$ is the relaxation rate at temperature T, and C_1 and C_2 are fitted constants. Equation (14) has been used not only for dielectric spectroscopy, but also for various dynamic mechanical and rheological data. Alternatively, the glass transition can be modeled with the Vogel–Fulcher equation[37,38] (Equation 15):

$$\log f(T) = A - \frac{B}{T - T_0} \tag{15}$$

where T_0 is the Vogel temperature (usually 30–70 °C below T_g) and A and B are fitted constants. The form of Equation (15) can be obtained by algebraic rearrangement of the WLF equation. For sub-glass relaxations, the relaxation rate is often better approximated with an Arrhenius relationship (Equation 16):

$$f(T) = C \exp\left(\frac{-E_a}{kT}\right. \tag{16}$$

where C is a fitted parameter and E_a is the apparent activation energy. Equations (14–16) are expressed in terms of relaxation rate; however, they can just as easily be written in terms of relaxation time (the inverse of relaxation rate).

For frequency domain data, there are several models that have been applied and these are briefly discussed in the remainder of this section. For more in-depth information, the interested reader should consult recent reviews by Havriliak and Havriliak.[14,39] Perhaps the simplest model for describing dielectric relaxation is the Debye model, which is based on a ''hindered'' reorientation of dipoles[2] (Equation 17):

$$\varepsilon_r = \varepsilon_U + \frac{\varepsilon_R - \varepsilon_U}{1 + iw\tau} \tag{17}$$

where ε_R and ε_U are the ''relaxed'' and ''unrelaxed'' permittivities, respectively, and τ is the characteristic relaxation time for reorientation of the dipoles. As mentioned in the previous section, both dipole reorientation and conduction mechanisms can be involved in the measured dielectric response so a term that includes conduction is often incorporated in the Debye model. Including this conduction term and splitting into real and imaginary components gives Equations (18) and (19):

$$\varepsilon'_r = \varepsilon_U + \frac{\varepsilon_R - \varepsilon_U}{1 + (w\tau)^2} \tag{18}$$

$$\varepsilon''_r = \frac{\sigma}{w\varepsilon_0} + \frac{(\varepsilon_R - \varepsilon_U)w\tau}{1 + (w\tau)^2} \tag{19}$$

These equations are plotted in Figure 11(a). The curves plotted correspond to the case where there is also some conduction (i.e. $\sigma > 0$), resulting in a low-frequency tail in the dielectric loss. Ignoring for now the conduction, the permittivity data show that ε_R corresponds to the relative permittivity at low frequencies when the dipoles can attain their maximum reorientation and ε_U is the permittivity at high frequencies when the dipoles are unable to keep up with the external field. The loss factor data, which are associated with energy absorption or damping by the material, indicate a peak at $w = 1/\tau$, which is the middle of the transition from ε_R to ε_U. While this model provides important insight into the nature of relaxation phenomena in polymers, it is qualitative at best. In fact, most relaxation phenomena do not have a single relaxation time, τ, as suggested by this model. Rather, they may have a distribution of relaxation times which makes modeling somewhat more complex.

Figure 11 (a) Plot of permittivity and loss factor for the Debye model (these data are plotted as a function of normalized frequency, $w\tau$). (b) Cole–Cole plot of the same data. The ''tail'' in complex permittivity plots indicated ion conduction.

Because few systems follow Debye behavior quantitatively, there have been a number of empirical generalizations made on Equations (17–19). One of the first was a generalization proposed by Cole and Cole.[40] Ignoring for now the contributions from ionic conductivity, Equation (17) can be re-written with an empirical fitting factor, α (Equation 20):

$$\varepsilon_r = \varepsilon_U + \frac{\varepsilon_R - \varepsilon_U}{1 + (iw\tau)^{1-\alpha}} \tag{20}$$

In addition to proposing this model, Cole and Cole also demonstrated the usefulness of a complex plane plot for representing the real and imaginary permittivity. These plots are commonly called Cole–Cole plots. They are similar to the complex impedance plots presented in the earlier section on instrumentation and sample preparation. They represent the data by plotting the imaginary permittivity, ε'' against the real permittivity, ε'. Figure 11(b) shows Cole–Cole plot representations of both the Debye model (Equation 17) and Cole and Cole's generalization (Equation 20). Whereas the Debye model data show a perfect semicircle, the Cole–Cole model allows for a compressed semicircle with its center below the ε' axis.

In addition to Cole and Cole, various researchers have suggested additional generalizations to the relaxation equations. For example, Fuoss and Kirkwood,[41] Davidson and Cole,[42] Jackle,[43] Williams and Watts,[44] Jonscher,[45] and Havriliak and Negami[46,47] have all proposed various generalizations to Equation (17). These equations are empirical in that they include one or two parameters for better fitting measured dielectric data. These equations are also nonlinear with respect to frequency, so nonlinear numerical regression methods must be applied in order to fit measured data to these various functions. If an investigator chooses to fit measured data to one of these models, then the choice of the ''best'' empirical model can depend on the nature of the dielectric relaxation being studied. In a recent review, Havriliak and Havriliak[48] have shown that the Havriliak–Negami equation does fit a wide range of data. It includes two empirical parameters, α and β, which allow for a Cole–Cole type of plot to have both flatness and unsymmetrical skew (Equation 21):

$$\varepsilon_r = \varepsilon_U + \frac{\varepsilon_R - \varepsilon_U}{[1 + (iw\tau)^{\alpha}]^{\beta}} \tag{21}$$

Havriliak and Havriliak also pointed out[48] the importance in providing details about the analysis methods used to fit measured data to a relaxation equation (i.e. convergence criteria, confidence intervals, etc.). In order to gain a better understanding of the sensitivity of the various fitted parameters, it is useful to use numerical experimentation. Such experiments can be accomplished by constructing additional input data sets with ''noise'' that reflects the measurement uncertainties of the original data. Only when these kinds of studies are done can data be intelligently understood in terms of the relaxation models.

4 APPLICATIONS AND METHODS

4.1 Detecting Relaxations

One of the most important aspects to characterizing the physical and mechanical properties of a polymer is its relaxation behavior. For an amorphous polymer, the glass transition temperature will determine if the polymer is to be a stiff glass or a soft rubber at its use temperature. When a polymer is semicrystalline, most engineering applications require that the polymer be used well below its melting temperature. Hence the positions of these transition temperatures are important also for optimizing processing conditions when manufacturing parts.

Other more subtle properties are also determined by relaxation behavior. For example, if a polymer is to be used for absorbing vibration, then it must have

a large amount of damping at the temperature and frequency of use. Conversely, if a polymer is to be used in applications such as transmission of electromagnetic energy, then the damping or loss should be minimized. Since relaxations are associated with energy absorption, the relative positions and intensities of a polymer's relaxation transitions are of great importance in these applications.

Dielectric spectroscopy can be particularly sensitive to molecular relaxations in polymers. Figure 12 shows the glass transition for amorphous PET, measured at 1 kHz.[49] The real part of the permittivity at low temperature is approximately 2.5, but then undergoes a step transition to a value of ~3 at high temperature. Thus, when the polymer is glassy, the dipoles are greatly inhibited in their motion and the permittivity has a relatively low value. When the polymer has softened, the dipoles can reorient much more easily and the permittivity can attain a much higher value. Figure 12 also shows the loss factor which is peaked at the center of the glass transition (~120 °C). The loss factor, which is indicative of the amount of damping or energy absorption by the polymer, shows that the polymer absorbs the most energy at a temperature that corresponds to the middle of the transition. The data in Figure 12 are permittivity as a function of temperature. It is also possible to obtain data at a single temperature as a function of frequency. The frequency-dependent data will show very similar features to the idealized Debye model in Figure 11(a). However, a better fit to the frequency-dependent data is usually obtained when a more general but semiempirical equation is used, such as the Havriliak–Negami equation (Equation 21). A useful resource that contains tables of dielectric relaxation parameters for a wide variety of polymers is the review by Havriliak and Havriliak.[14]

The electrical relaxation behavior measured by dielectric spectroscopy is analogous to the mechanical relaxation behavior measured by DMA. Both techniques show a step transition in the real part of the data and a peak in the imaginary part. However, whereas the real part of the dielectric permittivity goes from a low to a high value, the real part of the dynamic mechanical modulus goes in the opposite direction. Therefore, when dielectric data are compared with DMA data, it is common practice to convert the DMA data into mechanical compliance. Compliance as a function of frequency can also be fitted to relaxation equations such as the Havriliak–Negami function. Alternatively, the permittivity can be converted into "dielectric modulus" as defined in Equation (12). The dielectric modulus for PET measured at 1 kHz is shown in Figure 13. It should be noted that although the dielectric modulus is qualitatively analogous to mechanical modulus, it is by no means quantitatively equivalent. Furthermore, it is possible to have relaxations that are dielectrically strong but mechanically weak. Conversely, it is possible to have relaxations that are dielectrically weak or inactive, but mechanically strong. Hence dielectric spectroscopy and mechanical spectroscopy are complementary techniques for measuring the molecular relaxations of polymers.

The data in Figure 12 show only a single molecular relaxation, but it is possible for polymers to exhibit multiple relaxations. When measured over a broad temperature range or a broad frequency range, a polymer may show not only a glass transition (T_g), but also sub-T_g relaxations and a melting transition. While the relaxation spectra may be thought of as a "fingerprint" of a particular polymer, it is dependent on more than just the chemical structure. Factors such as morphology and thermal history can have a profound effect on the relaxation spectra, so they should be carefully considered or controlled

Figure 12 Glass transition of amorphous poly(ethylene terephthalate) (PET): permittivity.

Figure 13 Glass transition of amorphous PET: dielectric modulus.

when making measurements. For example, the relaxation peak positions and intensities are dependent on the temperature scan rate of the dielectric experiment, and also the thermal history of the polymer sample before the experiment was even begun.

Another instance in which there may be multiple relaxations is when a polymer is actually a heterogeneous mixture. Polymer mixtures or blends have become prevalent in modern engineering applications because they can have useful mechanical properties such as increased toughness. Most of these blends are multiphase, meaning that under a microscope, regions that are rich in one polymer are visibly separate from regions that are rich in a different polymer. It is therefore possible for a blend to have multiple glass transitions, each corresponding to a separate phase. There may be some limited miscibility, however, and the result of this miscibility is that there will be a corresponding shift in the position of each glass transition. On the other hand, if a blend is completely miscible, then there will only be a single phase, and therefore only a single glass transition.

The dielectric spectroscopy of partially miscible blends has been studied by Rellick and Runt,[50] and Figure 14 shows some representative data. Plotted are loss tangent curves of a blend of EVA and PVC after different thermal histories. Also shown are vertical lines that correspond to the glass transition temperatures of pure EVA and pure PVC. Because the blend is only partially miscible, the two separate T_gs are still evident, but they are each shifted by a finite amount from their pure values. The degree of mixing in each of these two phases can be calculated by applying the well-known Fox equation[51] (Equation 22):

$$\frac{1}{T_g} = \frac{w_1}{T_{g_1}} = \frac{w_2}{T_{g_2}} \tag{22}$$

where w_1 and w_2 are the respective weight fractions of the two components, T_{g_1} and T_{g_2} are their respective glass transition temperatures (i.e. in pure form), and T_g is the shifted glass transition temperature. Equation (22) is valid for homogeneous blends, but the example in Figure 14 is clearly a two-phase blend. However, if each phase is considered separately, then application of Equation (22) is still valid. Thus, if T_{g_1} and T_{g_2} are known, and since $w_2 = 1 - w_1$, the weight fractions in each phase can be calculated from the shifted glass transition temperatures.

One final aspect of the data in Figure 14 is the fact that the glass transitions shift more and more towards a central value as the mixture is held at higher temperature. Curve (d), which was blended without any supplementary heating, shows very little shift in the respective glass transitions. On the opposite end, the sample of curve (a) was heated at 105 °C for 12 h, and shows a much more pronounced shift in T_g values. Thus heating caused a migration of the polymer chains so that the two phases changed their compositions. Note that the data in Figure 14 are for amorphous polymers. When the polymers are semicrystalline, this technique only indicates the weight fractions in the respective amorphous phases.

Figure 14 Loss tangent curves at 100 kHz for 50% poly(ethylene-co-vinyl acetate) (EVA) and 50% poly(vinyl chloride) (PVC) blends with different thermal histories: (a) no heating; (b) 55 °C for 24 h; (c) 70 °C for 24 h; and (d) 105 °C for 12 h. 4.2 Cure and Process Monitoring

In the last 40 years, there has been substantial work published about dielectric measurements for the monitoring of polymer cure. Much of this work has been stimulated by the increasing importance of polymers and polymer matrix composites in engineering applications. Because of this extensive development, the dielectric technique has been refined to be more than just a laboratory measurement. With suitable electrodes it can be used to monitor polymerization in situ, particularly in thermosets.[52] Thus it is often used as a process control variable in industrial settings such as in batch reactors, presses, autoclaves, ovens, and molding operations.[27,53–55] Dielectric spectroscopy has even been used to monitor the ultraviolet cure of photopolymers.[56] Using data from dielectric sensors combined with sophisticated process models to control actively these various polymer processes is an active area of research.[57]

The dielectric monitoring of cure involves the measurement of the change of ion and dipole mobility in the resin as it polymerizes. The ion and dipole mobility is directly related to the viscosity of the resin, which is, in turn, a function of molecular weight or degree of cure. Dielectric spectroscopy has two distinct advantages over direct mechanical measurement of the viscosity. First, a mechanical viscosity measurement is usually limited to either low viscosities (i.e. viscometer or rheometer) or

high viscosities (i.e. DMA), whereas a dielectric measurement can continue over both regimes. Second, with the small, thin electrode sensors that are available today, dielectric analysis can monitor cure nondestructively, in situ, whereas mechanical techniques require a separate sample with a specific geometry.

Since dielectric monitoring of cure involves measurement of the ion and dipole mobility, the parameter of most interest is the resistance or resistivity. Figure 15 shows both the resistance and viscosity of an epoxy composite as it goes through a thermal cure cycle.[58] It shows that good qualitative agreement exists between the mechanical viscosity and dielectric resistance during the heating and curing of the composite. Physically, as the temperature is increased, viscosity and resistance both decrease because the ion mobility is higher. As the temperature approaches 175 °C, the polymerization reaction begins causing both the viscosity and resistance curves to change direction. This is because as the resin begins to solidify into a polymer, ion mobility decreases again. Although the data are shown as resistance, they could just as easily be plotted as resistivity, since they differ only in geometrical constants dependent on the experimental set-up.

While resistance and resistivity are scalar quantities that are defined only for zero frequency, an "apparent" resistance or resistivity can be computed at arbitrary frequency. More specifically, apparent resistivity, ρ, is the inverse of the apparent conductivity defined in Equation (17) (Equation 23):

$$\rho = \frac{1}{\sigma} = \frac{1}{w\varepsilon_0\varepsilon_r''} \tag{23}$$

An example of temperature-dependent resistivity for a sample of neat epoxy is plotted in Figure 16(a).[49] This sample underwent a linear temperature ramp of 5 °C min^{-1}. Similarly to Figure 15, the resistivity decreases with increases in temperature until the resin begins to polymerize into a solid. Then the resistivity increases again as ion mobility decreases. For completeness, Figure 16(b) shows the corresponding real and imaginary permittivities. As the temperature rises before cure, the loss factor increases owing to increasing ion mobility. As the cure proceeds, both the real and imaginary permittivity drop dramatically, indicating the formation of a polymer network that inhibits ion and dipole motion.

Because of the dramatic changes that can occur to the dielectric properties during cure, dielectric spectroscopy seems a natural technique for determining chemical kinetic rate constants. For example, kinetic information can be obtained by assuming a correlation between extent of cure and various dielectric data, such as logarithm of resistivity or relaxed permittivity. Vitrification can be determined by following the glass transition (e.g. with frequency domain, relaxation data). However, these concepts should be used with caution, since empirical correlations can be an oversimplification. The cure process can be complicated with multiple steps occurring simultaneously and a direct relationship between a

Figure 15 Resistance, R, and viscosity, η, of an epoxy composite during cure. Temperature was ramped from 24 to 175 °C at a nominal heating rate of 3 °C min^{-1}. [Reproduced by permission of the Society of Plastics Engineers from Y.A. Tajima, *Polym. Composites*, **3**(3), 162–169 (1982).]

Figure 16 (a) Apparent resistivity and loss tangent of an epoxy thermoset during thermal cure. (b) Real and imaginary permittivity of the same sample.

dielectric parameter and cure kinetics does not always exist. An excellent review of these issues is given by Senturia and Sheppard.[29]

4.3 Polymer Emulsions and Film Formation

Another important area of synthetic polymers where dielectric spectroscopy is useful is in the characterization of polymer latex emulsions. Because of its ease of application and environmental friendliness, the polymer latex has become a popular alternative to traditional solvent-based coatings. Characterization of these systems and their performance is an important problem for a large number of industrial applications. Dielectric spectroscopy is a useful technique for measuring certain aspects of these materials.

One such area were dielectric analysis has been proven effective is in the determination of latex particle size.[59] Figure 17(a) and (b) show the real and imaginary dielectric constant as a function of frequency for three different latex standards with diameters of 109, 497, and 1090 nm. It should be pointed out that these data were obtained with a four-electrode cell. This is because polymer latices contain highly mobile ions (high ionic conductivity), so the four-electrode cell helps to minimize blocking effects. In particular, separation of the ''driving'' electrodes from the ''sensing'' electrodes reduces the effect of ion accumulation on the measured signal. The data show that there is dielectric relaxation associated with these systems and that size is an important variable affecting the frequency where the relaxation is centered. Of course, there are other variables that can also affect both the center frequency and relative amplitude of the relaxation, including size distribution, solids content, temperature, and formulation. However, the data in Figure 17(a) and (b) demonstrate that under controlled conditions, dielectric spectroscopy can be used to measure rapidly particle sizes in polymer latices.

Dielectric analysis is also useful in the study of film formation or drying of polymer latices.[60,61] In recent work, Schultz and Chartoff[62] studied the drying of polymer latex films under various humidities. Figure 18 shows the conductance as a function of drying time for a typical sample film cast on interdigitated comb electrodes. Conductance, as opposed to conductivity defined in Equation (17), does not take the electrode geometry into account. Instead, it is calculated directly from the measured impedances. It is the inverse of the resistance defined in Equation (4). Hence it does not represent quantitative, geometry-independent data. The conductance data in Figure 18 could have been calculated at a fixed frequency. However, increased range and accuracy were obtained by fitting complex impedance plots of frequency scans and extrapolating the data to zero frequency. The data in Figure 18 show that there are several different stages of drying. These different drying stages are associated with different types of drying: fast evaporation, percolation, and diffusion. Hence the experimental data can be related to the underlying physical phenomena responsible for film formation. What is interesting about these data is that the quantitative values are unimportant. Rather, the relative trends and changes are often all that are required to enable a researcher to understand the material better.

Figure 17 (a) Real and (b) imaginary parts of the dielectric constant normalized by the weight fraction as a function of frequency for latex standards with diameters as indicated. [Reproduced from B.B. Sauer, R.S. Stock, K.-H. Lim, W.H. Ray, *J. Appl. Polym. Sci.*, **39**, 2419–2441 (1990), Copyright 1990 John Wiley & Sons Inc. Reprinted by permission of John Wiley & Sons, Inc.]

4.4 Humidity/Environmental Effects

Polymeric materials often undergo chemical and physical changes as a result of their environment. For example,

Figure 18 Conductance of a polymer latex film during drying.

radiation may cause cross-linking or chain scission in polymers, humidity may cause swelling because of water sorption, or polymers may age as a result of additive migration. Dielectric spectroscopy can provide a useful way to monitor these changes. In these types of studies, polymer samples may be measured at different times after exposure to different conditions, or a single polymer sample may be monitored continuously as it is undergoing change.

An example of environmentally induced change is shown in polymers studied by Maffezzoli et al.[63] and illustrated in Figure 19. In this case an epoxy matrix composite was immersed in water and an interdigitated comb electrode embedded between plies monitored the

Figure 19 Permittivity as a function of time during water absorption by an epoxy matrix composite at 20 °C. [Reproduced by permission of the Society of Plastics Engineers from A.M. Maffezzoli, L. Peterson, J.C. Seferis, J. Kenny, L. Nicolais, *Polym. Eng. Sci.*, **33**(2), 75–82 (1993).]

permittivity. The data show that the permittivity is initially constant because of the finite amount of time it takes for water to diffuse to the sensor position. After about 400 min, the permittivity begins to increase, and this is attributed to the increasing concentration of water molecules at the electrode. Eventually, the permittivity levels off as the concentration of water reaches saturation.

Interestingly, the curves also indicate that the permittivity experiences a sudden and dramatic increase after a sufficiently long time. The effect is most severe at lower frequencies. While this effect may seem puzzling at first, it is easily explained by electrode-blocking effects. As water is absorbed by the epoxy, the system swells, and ionic impurities that may be present in the material become more mobile. Thus, at low enough frequencies the electrodes may experience ionic polarization that leads to the anomalous upturn in the permittivity curves. While sudden and large changes in the permittivity may be an indicator of electrode-blocking effects, it is best to plot the complex impedance data as described in the instrumentation and sample preparation section of this article, in order to confirm that electrode blocking is occurring.

Other examples of environmental aging measurements include measurement of deterioration in dielectric insulation.[64] Specifically, dielectric loss factor measurements permit the diagnosis of aging from high-voltage stresses. As a final example, Kranbuehl et al.[65] studied the use of an interdigitated electrode as an in situ monitor of the state of polymer coatings exposed to acids. The advantage to this type of in situ dielectric sensing is that measurements can be made without interrupting the experiment or process.

4.5 Analysis of Composites

A final application of dielectric spectroscopy that has received considerable attention is in the evaluation of composites. Polymer matrix composites can be filled with continuous fibers, chopped fibers, platelets, and even simple fillers such as carbon black or sand. The synergistic properties that result from these mixtures result in a wide array of polymer-based materials with advantageous properties. Understanding the composite dielectric behavior is important for both scientific and practical reasons.

Three important issues that must be considered in composites are their homogeneity, microstructure, and anisotropy. Homogeneity concerns the length scales of the constituent materials. When measuring composites with a dielectric apparatus, the sample size (e.g. separation between electrodes and area of electrodes) must be much larger than the size of the largest constituent dimension within the composite, otherwise an ''average'' response

is not being measured. When measuring moderately conductive materials such as carbon black-filled polymers, microstructure becomes an important issue. In particular, the actual arrangement of the carbon black distributed within the polymer matrix may form a network that can create conduction paths and these paths may be anisotropic. The distribution of constituents within a matrix is highly dependent on the processing conditions and thermal history. To address microstructure issues properly, it is often necessary to include some form of microscopy along with the dielectric measurement of composites. This allows an investigator to tie the dielectric response directly to these important physical factors.

The third issue, anisotropy, is concerned with the orientation of the constituents in a composite. For example, a continuous fiber composite will have dielectric properties that are different depending on the orientation of the sample within the electrodes. If there are particles within a polymer matrix with an anisotropic shape, then they may be oriented because of processing and this too will cause an anisotropic response depending on the alignment. It should also be noted that anisotropy can occur in neat polymers in addition to composites. Drawing or pressing processes can result in anisotropic dielectric properties in amorphous and semicrystalline polymers. However, more dramatic anisotropy can be found in liquid crystalline polymers,[66] which are sometimes termed 'in-situ' composites. The anisotropy in the dielectric permittivity can even be used to estimate quantitatively the degree of alignment in these types of systems.[67] When there is dielectric anisotropy in neat polymers or composites, the orientation of the sample with respect to the measuring electric field must be considered. With parallel-plate electrodes, the electric field orientation is perpendicular to the plane of the electrodes. Several samples made with different orientations may be necessary to characterize fully the permittivity in these materials.

In order to design new composites and understand current ones, it is useful to construct mathematical models that describe these materials. There are a number of theoretical equations for relating constituent properties to the average dielectric response of the composite. Because of the complexity of issues described above, most of these theories assume a homogeneous and isotropic material. Two of the best known theories were originally developed by Bruggeman and Maxwell–Garnett. These theories and all their relatives are collectively known as effective medium theories.

The Maxwell–Garnett theory[68] assumes spherical inclusions, phase a, are completely surrounded by a matrix, phase b. The average permittivity (ε) is then related to the permittivities of phase a (ε_a) and phase b (ε_b) by Equation (24):

$$\frac{\varepsilon - \varepsilon_b}{\varepsilon + 2\varepsilon_b} = v_a \frac{\varepsilon_a - \varepsilon_b}{\varepsilon_a + 2\varepsilon_b} \tag{24}$$

where v_a is the volume fraction of phase a. In contrast to this matrix-inclusion formulation, the Bruggeman effective medium theory[69] assumes that the phases are distributed symmetrically, resulting in Equation (25):

$$0 = v_a \frac{\varepsilon_a - \varepsilon}{\varepsilon_a + 2\varepsilon} + v_b \frac{\varepsilon_b - \varepsilon}{\varepsilon_b + 2\varepsilon} \tag{25}$$

A good physical understanding of effective medium theories can be obtained from a review by Aspnes.[70] In addition, Equations (24) and (25) are only a small sample of the various equations for modeling composite dielectric response. There are numerous other theories that account for particle shape, orientation, microstructure, and many other factors.[71]

ACKNOWLEDGMENTS

I would like to express thanks to Mary Galaska of the University of Dayton for her help in acquiring some of the example data. I also wish to express gratitude to Dr Richard Chartoff of the University of Dayton for his various suggestions.

LIST OF SYMBOLS

A	electrode area
a	inner radius of cylindrical electrodes
b	outer radius of cylindrical electrodes
C	capacitance
d	distance between electrodes
E_a	apparent activation energy
f	frequency (in hertz)
i	denotes imaginary number ($i = \sqrt{-1}$)
I	current
I_0	current amplitude
l	length of cylindrical electrodes
M	dielectric modulus ($M = M' + iM''$)
M'	real part of dielectric modulus
M''	imaginary part of dielectric modulus
R	resistance
t	time
T_g	glass transition temperature
V	voltage
V_0	voltage amplitude
v_i	volume fraction
w_i	weight fraction
Z	complex impedance (ratio of voltage to current)

Z'	real part of the impedance
Z''	imaginary part of the impedance
α	empirical parameter used in Havriliak–Negami and Cole–Cole equations for dielectric relaxation
β	empirical parameter used in Havriliak–Negami equation for dielectric relaxation
δ	phase shift
ε	permittivity (also used as shorthand notation for relative permittivity, ε_r)
ε_0	permittivity of vacuum (8.854×10^{-12} F m^{-1})
ε_r	relative permittivity
ε_R	''relaxed'' permittivity (permittivity measured at low frequencies – used in relaxation models)
ε_U	''unrelaxed'' permittivity (permittivity measured at high frequencies – used in relaxation models)
ε'	real part of complex permittivity
ε''	imaginary part of complex permittivity (dielectric loss factor)
η	viscosity
σ	conductivity
w	angular frequency (in rad s^{-1})

ABBREVIATIONS AND ACRONYMS

DMA	Dynamic Mechanical Analysis
EVA	Poly(ethylene-co-vinyl acetate)
PET	Poly(ethylene terephthalate)
PVC	Poly(vinyl chloride)
TSC	Thermally Stimulated Current

Dynamic mechanical analysis (DMA) is the technique of applying a stress or strain to a sample and analyzing the response to obtain phase angle and deformation data. These data allow the calculation of the damping or tan δ; the storage, loss, and complex modulus; as well as complex viscosity and complex compliance. Two approaches are used: (i) forced frequency, where the signal is applied at a set frequency and (ii) free resonance, where the material is perturbed and allowed to exhibit free resonance decay. Most modern DMA instruments are of the forced resonance type. In both approaches, the technique is very sensitive to the motions of the polymer chains and it is a powerful tool for measuring transitions in polymers. It is estimated to be 100 times more sensitive to the glass transition than differential scanning calorimetry (DSC) and resolves other more localized transitions not detected in DSC. In addition, the technique allows the rapid scanning of a material's modulus and viscosity as a function of temperature or frequency. DMA may also be referred to as dynamic mechanical thermal analysis (DMTA), dynamic mechanical spectroscopy (DMS), or dynamic thermomechanical analysis (DTMA).

1 INTRODUCTION AND HISTORY OF DYNAMIC MECHANICAL ANALYSIS

DMA is a very important tool in the modern polymer laboratory. Despite that, only a few books have concentrated on the technique.[1–3] The first attempts to carry out oscillatory experiments to measure the elasticity of a material were made by Poynting[4] in 1909. Other early works gave methods to apply oscillatory deformations by various means to study metals,[5] and many early experimental techniques were reviewed by te Nijenhuis[6] in 1978. Miller's book on polymer properties[7] referred to dynamic measurements in this early discussion of molecular structure and stiffness. Early commercial instruments included the Weissenberg rheogoniometer (~1950) and the Rheovibron (~1958). The Weissenberg rheogoniometer, which dominated cone-and-plate measurements for over 20 years following 1955, was the commercial version of the first instrument to measure normal forces.[8] By the time Ferry wrote the *Viscoelastic Properties of Polymers*[9] in 1961, dynamic measurements were an integral part of polymer science and he gives the best development of the theory available. In 1967, McCrum et al.[10] collected the current information on DMA and dielectric analysis (DEA) in their landmark textbook. The technique remained fairly specialized until the late 1960s when commercial instruments became more user friendly. Around 1966, Gillham developed the torsional braid analyzer (TBA),[11] which started the modern period of DMA. In 1971, Macosko and Starita[12] built a DMA instrument that measured normal forces, and from this came the Rheometrics Corporation. In 1976, Bohlin also developed a commercial DMA and started Bohlin Rheologia. Both instruments used torsional geometry. The early instruments were, regardless of manufacturer, difficult to use, slow, and limited in their ability to process data. In the late 1970s, Murayama[13] and Read and Brown[14] wrote books on the uses of DMA for material characterization. Several thermal and rheological instrument companies introduced DMA instruments in the same time period and currently most thermal and rheological vendors offer some type of DMA device.

Polymer Laboratories offered a DMA instrument using an axial geometry in the early 1980s. This was soon

followed by an instrument from Du Pont. PerkinElmer developed a controlled stress analyzer based on their thermomechanical analyzer (TMA) technology, which was designed for increased low-end sensitivity. In 1990 and early 2000, the latest wave of DMA devices came out, adding the capability to handle samples in solution, immersion, and exposure to UV light.[15] The competition between vendors has led to easier-to-use, faster, and less expensive instruments. The revolution in computer technology, which has so much affected the laboratory, changed the latter, and DMA instruments of all types became more user-friendly as computers and software evolved.

2 THEORY AND OPERATING PRINCIPLES

2.1 Forced Frequency Analyzers

If a constant load applied to a sample begins to oscillate sinusoidally (Figure 1), the sample will deform sinusoidally. This will be reproducible if the material is deformed within its linear viscoelastic region. For any one point on the curve, the stress applied is described by Equation (1):

$$\sigma = \sigma_0 \sin \omega t \tag{1}$$

where σ is the stress at time t, σ_0 is the maximum stress, ω is the frequency of oscillation, and t is time. The resulting strain wave shape will depend on how much viscous behavior and how much elastic behavior the sample has. In addition, the rate of stress can be determined by taking the derivative of the above-mentioned equation

Figure 1 When a sample is subjected to a sinusoidal oscillating stress, it responds with a similar strain wave provided the material stays within its elastic limits. (Reproduced with permission of Taylor & Francis Group LLC.)

with respect to time:

$$\frac{d\sigma}{dt} = \omega\sigma_0 \cos \omega t \tag{2}$$

The two extremes of the material's behavior, elastic and viscous, provide the limits that will sum to give the strain wave. The behavior can be understood by evaluating each of the two extremes. The material at the spring-like or Hookean limit will respond elastically with the oscillating stress. The strain at any time can be written as Equation (3):

$$\varepsilon(t) = E\sigma_0 \sin(\omega t) \tag{3}$$

where $\varepsilon(t)$ is the strain at any time t, E is the modulus, σ_0 is the maximum stress at the peak of the sine wave, and ω is the frequency. Since in the linear region σ and ε are linearly related by E, the relationship is given by Equation (4):

$$\varepsilon(t) = \varepsilon_0 \sin(\omega t) \tag{4}$$

where ε_0 is the strain at the maximum stress. This curve, shown in Figure 2(a), has no phase lag (or no time difference from the stress curve) and is called the *in-phase portion* of the curve.

The viscous limit was expressed as one in which the stress is proportional to the strain rate, which is the first derivative of the strain. This is best modeled by a dashpot, and for that element the term for the viscous response in terms of strain rate is described by Equation (5):

$$\varepsilon(t) = \eta\frac{d\sigma_0}{dt} = \eta\omega\sigma_0 \cos(\omega t) \tag{5}$$

or Equation (6):

$$\varepsilon(t) = \eta\omega\sigma_0 \sin\left(\omega t + \frac{\pi}{2}\right) \tag{6}$$

where the terms are as above and η is the viscosity. Substituting terms as above gives Equation (7):

$$\varepsilon(t) = \omega\sigma_0 \cos(\omega t) = \omega\sigma_0 \sin\left(\omega t + \frac{\pi}{2}\right) \tag{7}$$

This curve is shown in Figure 2(b). Now consider the behavior of the material that lies between these two limits. This curve is shown in Figure 2(c), which is intermediate between the above-mentioned cases. The difference between the applied stress and the resultant strain is an angle δ, and this must be added to the equations. Hence, the elastic response at any time can now be written as Equation (8):

$$\varepsilon(t) = \varepsilon_0 \sin(\omega t + \delta) \tag{8}$$

Figure 2 When the material responds to the applied wave perfectly elastically, an in-phase response is seen (a), while a viscous response gives an out-of-phase response (b). Viscoelastic materials fall in between these two lines as shown in (c). (With permissions from PerkinElmer Life and Analytical Sciences, Shelton, CT.)

Using trigonometry, this can be rewritten as Equation (9):

$$\varepsilon(t) = \varepsilon_0[\sin(\omega t)\ \cos\ \delta + \cos(\omega t)\ \sin\ \delta] \tag{9}$$

This equation, corresponding to the curve in Figure 2(c), can be separated into the in-phase and out-of-phase strains that correspond to curves such as those in Figure 2(a) and (b), respectively. These sum to the curve in Figure 2(c) and are given by Equations (10) and (11):

$$\varepsilon' = \varepsilon_0\ \sin(\delta) \tag{10}$$

$$\varepsilon'' = \varepsilon_0\ \cos(\delta) \tag{11}$$

And the vector sum of these two components gives the overall or complex strain on the sample (Equation 12):

$$\varepsilon^* = \varepsilon' + i\varepsilon'' \tag{12}$$

2.2 Free Resonance Analyzers

If a suspended sample can swing freely, it will oscillate like a harp or guitar string until the oscillations gradually come to a stop. The naturally occurring damping of the material controls the decay of the oscillations. This produces a wave, shown in Figure 3, which is a series of sine waves decreases in amplitude and frequency. Several methods exist to analyze these waves and are covered in a review by Gillham.[16,17] These methods have also been applied successfully to the recovery portion of a creep-recovery curve, in which the sample goes into free resonance on removal of the creep force.[18,19]

From the decay curve, the period T and the logarithmic decrement Λ can be calculated. Several methods exist for

Figure 3 The decay wave from a free resonance analyzer shows the decrease in amplitude of signal with time. (Reproduced with permission of Taylor & Francis Group LLC.)

both manual and digital processing.[16,17,20] Fuller details of the following may be found in McCrum et al.[20] and Gillham.[16,17] Basically, the decay of the amplitude is evaluated over as many swings as possible to reduce error (Equation (13)):

$$\Lambda = \frac{1}{j} \ln \left(\frac{A_n}{A_{n+j}} \right) \tag{13}$$

where j is the number of swings and A_n is the amplitude of the nth swing. For one swing, where $j = 1$, the above equation becomes Equation (14):

$$\Lambda = \ln \left(\frac{A_n}{A_{n+j}} \right) \tag{14}$$

If for a low value of Λ, where $A_n/A_{n+1} \approx 1$, the equation can be rewritten as

$$\Lambda \approx \frac{1}{2} \left(\frac{A_n^2 - A_{n+1}^2}{A_n^2} \right) \tag{15}$$

then from this, since the square of the amplitude is proportional to the stored energy, $\Delta W / W_{\text{st}}$, and the stored energy can be expressed as $2\pi \tan \delta$, this equation becomes Equation (16):

$$\Lambda \approx \frac{1}{2} \left(\frac{\Delta W}{W_{\text{st}}} \right) = \pi \tan \delta \tag{16}$$

which gives us the phase angle δ. The time of the oscillations, the period T, can be found using the Equation (17):

$$T = 2\pi \sqrt{\frac{M}{\Gamma_1}} \sqrt{\frac{1 + \Lambda^2}{4\pi^2}} \tag{17}$$

where Γ_1 is the torque for one cycle and M is the moment of inertia around the central axis. Alternatively, T can be calculated directly from the plotted decay curve as Equation (18):

$$T = \left(\frac{2}{n} \right) (t_n - t_0) \tag{18}$$

where n is the number of cycles and t is the time. From this, the shear modulus, G, can be calculated, which for a rod of length L and radius r is given by Equation (19):

$$G = \left(\frac{4\pi^2 ML}{NT^2} \right) \left(1 + \frac{\Lambda^2}{4\pi^2} \right) - \frac{mgr}{12N} \tag{19}$$

where m is the mass of the sample, g is the gravitational constant, and N is a geometric factor. In the same system, the storage modulus, G', can be calculated using Equation (20):

$$G' = \left(\frac{1}{T^2} \right) \left(\frac{8\pi ML}{r^4} \right) \tag{20}$$

Having the storage modulus and the tangent of the phase angle, the remaining dynamic properties can be calculated.

Free resonance analyzers normally are limited to rod-shaped or rectangular samples or materials that can be impregnated on to a braid. This last approach is how the curing studies on epoxy and other resin systems are done in torsion, which gives these instruments the name TBA.

3 INSTRUMENTATION

One of the biggest choices when selecting a DMA instrument is to decide whether to use stress (force) or strain (displacement) control for applying the deforming load to the sample (Figure 4a and b). Strain-controlled analyzers, whether for simple static testing or for DMA, move the probe to a set distance and use a force balance transducer or load cell to measure the stress. These parts are typically located on different shafts. The simplest version of this is a screw-driven tester, where the sample is pulled one turn. This requires very large motors, so the available force always exceeds what is needed. They normally have better short-time response for low-viscosity materials and can perform

Figure 4 Types of forced resonance DMA instruments: (a) axial, (b) torsional, (c) controlled stress, and (d) controlled strain. (Reproduced with permission of Taylor & Francis Group LLC.)

stress–relaxation experiments easily. They also usually can measure normal forces if they are arranged in torsion. A major disadvantage is that their transducers may drift at long times or with low signals.

Stress-controlled analyzers are cheaper to make because there is only one shaft, but are somewhat trickier to use. Many of the difficulties have been alleviated by software and many strain-controlled analyzers on the market are really stress-controlled instruments with feedback loops, making them act as if they were strain controlled. In stress control, a set force is applied to the sample. As temperature, time, or frequency varies, the applied force remains the same. This may or may not be the same stress: in extension, for example, the stretching and necking of a sample will change the applied stress seen during the run. However, this constant stress is a more natural situation in many cases and it may be more sensitive to material changes. Good low-force control means that they are less likely to destroy any structure in the sample. Long relaxation times or long creep studies are more easily performed on these instruments. Their greatest disadvantage is that their short-time responses are limited by inertia with low-viscosity samples.

Since most DMA experiments are run at very low strains (~0.5% maximum) so as to stay well within a polymer's linear region, it has been reported that both analyzers give the same results.[21] However, when one reaches the nonlinear region, the difference becomes significant as stress and strain are no longer linearly related. Most of the instruments on the market today are stress-controlled analyzers that mimic strain control by a feedback loop. For most users, this is not a problem but if one is interested in the nonlinear regions, it should be considered.

DMA instruments are normally built to apply the stress or strain in two ways (Figure 4c and d). One can apply force in a twisting motion, so that one is testing the sample in torsion. This type of instrument is the dynamic analog of the constant-shear, spinning-disk rheometers. While mainly used for liquids and melts, solid samples may also be tested by twisting a bar of the material. Torsional analyzers normally also permit continuous shear and normal force measurements. Most of these analyzers can also do creep–recovery, stress–relaxation, and stress–strain experiments.

Axial analyzers are normally designed for solid and semisolid materials and apply a linear force to the sample. These analyzers are usually associated with flexure, tensile, and compression testing, but they can be adapted to do shear and liquid specimens by proper choice of fixtures. Sometimes the instrument's design makes this inadvisable, however (e.g. working with a very fluid material in a system where the motor is underneath the sample and has the potential to damage the instrument if the sample spills into the motor). These analyzers can normally test higher modulus materials than torsional analyzers and can run TMA studies in addition to creep–recovery, stress–relaxation, and stress–strain experiments. Recent advances in sample handling techniques have made it possible for these instruments to handle both lower viscosity samples and powders.[1,15,22]

Despite the traditional selection of torsional instruments for melts and liquids and axial instruments for solids, there is really considerable overlap between these types of instruments. With the proper choice of sample geometry and good fixtures, both types can handle similar samples, as shown by the use of both types to study the curing of neat resins. Normally, axial analyzers cannot handle fluid samples below about 500 Pa s and torsional instruments will top out with the harder samples (the exact modulus depending on the size of the motor and/or load cell).

4 APPLICATIONS

4.1 Thermoplastic Solids and Cured Thermosets

The thermal transitions in polymers can be described in terms of either free volume changes[23] or relaxation times.[24] While the latter tend to be preferred by engineers and rheologists in contrast to chemists and polymer physicists who lean toward the former, both descriptions are equivalent. Changes in free volume, v^f, can be monitored as a volumetric change in the polymer, by the absorption or release of heat associated with that change, the loss of stiffness, increased flow, or a change in relaxation time.

The free volume of a polymer, v^f, is known to be related to viscoelasticity,[25,26] aging,[27–30] penetration by solvents,[31] and impact properties.[32] Defined as the space that a molecule has for internal movement, it is shown schematically in Figure 5(a). A simple approach to looking at free volume is the crankshaft mechanism,[33] where the molecule is imagined as a series of jointed segments. From this model, it is possible to describe simply the various transitions seen in a polymer. Other models exist that allow for higher precision in describing the behavior: the best seems to be the Doi and Edwards model.[34] Aklonis and MacKnight[35] give a good summary of the available models, as does Rohn.[36]

The crankshaft model treats the molecule as a collection of mobile segments that have some degree of free movement. This is a very simplistic approach, yet very useful for explaining the behavior. As the free volume of the chain segment increases, its ability to move in various directions also increases (Figure 5b). This increased

Figure 5 Free volume, v^f, in polymers: (a) the relationship of free volume to transitions and (b) a schematic example of free volume and the crankshaft model. Below the T_g in (a), various paths with different free volumes exist depending on heat history and processing of the polymer, where the path with the least free volume is the most relaxed. (b) The various motions of a polymer chain. Unless enough free volume exists, the motions cannot occur. (Reproduced with permission of Taylor & Francis Group LLC.)

mobility in either side chains or small groups of adjacent backbone atoms results in a greater compliance (lower modulus) of the molecule. These movements have been studied, and Heijboer[37] classified β and γ transitions by their type of motions. The specific temperature and frequency of this softening help drive the end use of the material.

Moving from very low temperature, where the molecule is tightly compressed, to higher temperatures, the first changes are the solid-state transitions. This process is shown in Figure 6. As the material warms and expands, the free volume increases so that localized bond movements (bending and stretching) and side-chain movements can occur. This is the γ transition, at temperature T_γ, which may also involve associations with water.[38] As the temperature and the free volume continue to increase, the whole side chains and localized groups of four to eight backbone atoms begin to have enough space to move and the material starts to develop some toughness.[39] This transition, called the *β transition*, at temperature T_β, is not as clearly defined as described here (Figure 6). Often it is the glass transition, T_g, of a secondary component in a blend or of a specific block in a block copolymer. However, a correlation with toughness is seen empirically.[40]

As heating continues, T_g or the glass transition appears, when the chains in the amorphous regions begin to coordinate large-scale motions (Figure 6). One classical description of this region is that the amorphous regions have begun to melt. Since T_g occurs only in amorphous

Figure 6 Idealized temperature scan of a polymer. Starting at low temperature, the modulus decreases as the molecules gain more free volume, resulting in more molecular motion. This shows the main curve as divided into six regions that correspond to local motions (6), bond bending and stretching (5), movements in the side chain or adjacent atoms in the main chain (4), the region of T_g (3), coordinated movements in the amorphous portion of the chain (2), and the melting region (1). Transitions are marked as described in the text. (Reproduced with permission of Taylor & Francis Group LLC.)

material, in a 100% crystalline material there would not be a T_g. Continued heating drives the material through the T_α^* and T_{ll}. The former occurs in a crystalline or semicrystalline polymer and is a slippage of the crystallites past each other. The latter is a movement of coordinated segments in the amorphous phase that relates to reduced viscosity. These two transitions are not universally accepted. Finally, the melt is reached and large-scale chain slippage occurs and the material flows. This is the melting temperature, T_m. For a cured thermoset, nothing happens after T_g until the sample begins to burn and degrade because the cross-links prevent the chains from slipping past each other.

This brief overview provides an idea of how an idealized polymer responds. Now a more detailed description of these transitions can be provided with some examples of their applications. The best general collection of this information is still McCrum et al.'s 1967 text.[33]

4.1.1 *Sub-T_g Transitions*

The area of sub-T_g or higher-order transitions has been extensively studied,[41–48] as these transitions are associated with mechanical properties. These transitions can sometimes be seen by DSC and TMA, but they are normally too weak or too broad to be determined by these methods. DMA, DEA, and similar techniques are usually required.[49] Some authors have also called these types of transitions[50,51] *second-order transitions* to differentiate them from the primary transitions of T_m and T_g, which involve large sections of the main chains. Boyer reviewed T_β in 1968[52] and pointed out that while a correlation often exists, T_β is not always an indicator of toughness. Bershtein and Egorov[53] have reported that this transition can be considered the 'activation barrier' for solid-phase reactions, deformation, flow or creep, acoustic damping, physical aging changes, and gas diffusion into polymers, as the activation energies for the transition and these processes are usually similar. The strength of these transitions is related to how strongly a polymer responds to those processes. These sub-T_g transitions are associated with the material properties in the glassy state. In paints, for example, peel strength (adhesion) can be estimated from the strength and frequency dependence of the subambient β transition.[54] Nylon 6,6 shows a decreasing toughness, measured as impact resistance, with declining area under the T_β peak in the tan δ curve. Figure 7 shows the relative differences in T_β compared with T_g for high-impact and low-impact nylon. It has been shown, particularly in cured thermosets, that increased freedom of movement in side chains increases the strength of the transition. Cheng et al.[55] reported for rigid rod polyimides that the

The (a) lines show a material with good impact strength by the falling dart test and the (b) lines show one with poor values by the same test. (Reproduced with permission of Taylor & Francis Group LLC.)

β transition is caused by the noncoordinated movement of the diamine groups, although the link to physical properties was not investigated. Johari et al. reported from both mechanical[56] and dielectric studies[57] that both the β and γ transitions in bisphenol A–based thermosets depend on the side chains and unreacted ends, and that both are affected by physical aging and post cure. Nelson[58,59] reported that these transitions can be related to vibration damping. This is also true for acoustic damping.[60] In both these cases, the strength of the β transition is taken as a measurement of how effectively a polymer will absorb vibrations. There is some frequency dependence involved in this, which will be discussed later in Section 5.7.

Boyer[61] and Heijober[37] showed that this information needs to be considered with care, as not all β transitions correlate with toughness or other properties. This can be due to misidentification of the transition or because the transition does sufficiently disperse energy. A working rule of thumb[62–66] is that the β transition must be related to either localized movement in the main chain or very large side-chain movement to absorb sufficient energy. The relationship of large side-chain movement and toughness has been extensively studied in polycarbonate by Yee and Smith[67] and also in many other tough glassy polymers.[68]

Less use is made of the T_γ transitions and they are mainly studied to understand the movements occurring in polymers. Wendorff and Schartel[69] report that this transition in polyacrylates is limited to inter- and intramolecular motions within the scale of a single repeat unit. Both McCrum et al.[33] and Boyd[70] limited T_γ and T_δ similarly to very small motions either within the molecule or with bound water. The use of what is called *two-dimensional infrared* (IR) *spectroscopy*, which couples Fourier transform infrared (FTIR) or Raman spectroscopy and DMA to study these motions, is a topic of current interest.[71,72] This couple can also be used to

Figure 8 Definition of operating range based on position of T_g and T_β in a cured epoxy silica composite.

study the curing of various materials in which the modulus does not track linearly with the degree of cure.[73]

4.1.2 *The Glass Transition (T_g or T_α)*

As the free volume continues to increase with increasing temperature, the glass transition, T_g, occurs where large segments of the chain start moving. This transition is also called the *α transition*, T_α. T_g is very dependent on the degree of polymerization up to a value known as the *critical* T_g or the *critical molecular weight*. Above this value, T_g typically becomes independent of molecular weight.[74] T_g represents a major transition for many polymers, as the physical properties changes drastically as the material goes from a hard glassy to a rubbery state. It defines one end of the temperature range over which the polymer can be used, often called the *operating range of the polymer*, and an example of this range is shown in Figure 8. Where strength and stiffness are needed, it is normally the upper limit for use. In rubbers and some semicrystalline materials such as polyethylene and polypropylene, it is the lower operating temperature. Changes in T_g are commonly used to monitor changes in the polymer such as plasticizing by environmental solvents and increased cross-linking from thermal or ultraviolet (UV) aging.

T_g of cured materials or thin coatings is often difficult to measure by other methods, and more often than not the initial cost justification for a DMA is measuring a hard-to-find T_g. While estimates of the relative sensitivity of DMA with respect to DSC or differential thermal analysis (DTA) vary, it appears that DMA is 10–100 times more sensitive to the changes occurring at T_g. The T_g in highly cross-linked materials can easily be seen long after it has become too flat and diffuse to be seen in the DSC (Figure 9). A highly cross-linked molding resin

Figure 9 The T_g of a chip encapsulation material as measured by DSC and DMA as a function of postcure time. (Reprinted with permission from K. Menard, *Dynamic Mechanical Analysis: A Practical Introduction*, CRC Press, Boca Raton, FL, 1999.)

used for chip encapsulation was run by both methods, and DMA was able to detect the transition after it was undetectable in DSC.[1] This is also a known problem with certain materials such as medical-grade urethanes and very highly crystalline polyethylenes.[15]

The method of determining T_g in DMA can be a matter for disagreement, as at least five ways are currently in use (Figure 10a). It should be noted that DSC also has multiple methods (Figure 10b). Depending on the industry standards or the background of the operator, the peak or onset of the tan δ curve, the onset of the E' drop, or the onset or peak of the E'' curve may be used. The values obtained from these methods can differ by up to 25 °C from each other in the same run. In addition, a 10–20 °C difference from DSC is also seen in many materials. In practice, it is important to specify exactly how the T_g should be determined. For DMA, this means defining the heating rate, applied stresses (or strains), the frequency used, and the method of determining T_g. For example, the sample will be run at 10 °C min^{-1} under 0.05% strain at 1 Hz in a nitrogen

Figure 10 Methods of determining T_g. (a) Multiple methods of determining T_g are shown for DMA. T_g varies by up 10 °C in this example, depending on the value chosen. Differences as great as 25 °C have been reported. (b) Four of the methods used to determine T_g in DSC are shown. The half-height and half-width methods are not included. (Reproduced with permission of Taylor & Francis Group LLC.)

purge (20 $cm^3\,min^{-1}$) and the T_g determined from the peak of the tan δ curve.

It is not unusual to see a peak or hump on the storage modulus directly preceding the drop that corresponds to the T_g. This is shown in Figure 11. This is also seen in the DSC and DTA and corresponds to a rearrangement in the molecule to relieve stresses frozen in below T_g by the processing method. These stresses are trapped in the material until enough mobility is obtained at T_g to allow the chains to move to a lower energy state. Often a material will be annealed by heating it above T_g and cooled to remove this effect. For similar reasons, some experimenters will run a material twice or use a heat–cool–heat cycle to eliminate processing effects.

4.1.3 *The Rubbery Plateau, T_α^* and T_{ll}*

The area above the T_g and below the melt is known as the *rubbery plateau*, and its length and viscosity are dependent on the molecular weight between entanglements (M_e)[75] or cross-links. The molecular weight between entanglements is normally calculated during a stress–relaxation experiment but similar behavior is observed in DMA. The modulus in the plateau region is proportional to either the number of cross-links or the chain length between entanglements. This is often expressed in shear as Equation (21):

$$G' \approx \frac{\rho RT}{M_e} \tag{21}$$

where G' is the shear storage modulus of the plateau region at a specific temperature, ρ is the polymer density, and M_e is the molecular weight between entanglements. In practice, the relative modulus of the plateau region shows the relative changes in M_e or the number of cross-links compared with a standard material.

The rubbery plateau is also related to the degree of crystallinity in a material, although DSC is a better method for characterizing crystallinity than DMA.[76,77] Also as in DSC, there is evidence of cold crystallization in the temperature range above T_g (Figure 12). That is one of several transitions that can be seen in the rubbery plateau region. This crystallization occurs when the polymer chains have been quenched (quickly cooled)

Figure 11 Stress relief at T_g in DMA. The overshoot is similar to that seen in DSC and is caused by molecular rearrangements that occur owing to the increased free volume at the transition. (Reproduced with permission of Taylor & Francis Group LLC.)

Figure 12 Cold crystallization in poly(ethylene terephthalate) causing a large increase in the storage modulus, E', above T_g. A DSC scan of the same material is included. (Reproduced with permission of Taylor & Francis Group LLC.)

into a highly disordered state. On heating above T_g, these chains gain enough mobility to rearrange into crystallites, which causes sometimes a dramatic increase in modulus. DSC or its temperature-modulated variant, dynamic differential scanning calorimetry (DDSC), can be used to confirm this.[78–81] The α^* transition, T_α^*, the liquid–liquid transition, T_{ll}, the heat set temperature, and the cold crystallization peak are all transitions that can appear on the rubbery plateau. In some crystalline and semicrystalline polymers, a transition called the α^* *transition* (T_α^*) is seen.[82,83] Figure 13 shows this in a sample of polypropylene. The α^* transition is associated with the slippage between crystallites, which helps extend the operating range of a material above T_g. This transition is very susceptible to processing-induced changes and can be enlarged or decreased by the applied heat history, processing conditions, and physical aging.[84,85] T_α^* has been used by fiber manufacturers to optimize properties in their materials.

In amorphous polymers, the T_{ll} transition is seen instead, which is a liquid–liquid transition associated with increased chain mobility and segment–segment

Figure 13 The α^* transition, T_α^*, in polypropylene corresponding to a crystal–crystal slip in the polymer. (Reproduced with permission of Taylor & Francis Group LLC.)

associations.[86] This order is lost when T_{ll} is exceeded and regained on cooling from the melt. Boyer[87–89] reported that, like T_g, the appearance of T_{ll} is affected by the heat history. T_{ll} is also dependent on the number-average molecular weight, M_n, but not on the weight-average molecular weight, M_w. Bershtien et al.[90] suggest that this may be considered as quasimelting on heating or the formation of stable associates of segments on cooling. While this transition is reversible, it is not always easy to see, and Boyer[87] spent many years trying to prove it was real. Not everyone accepts the existence of this transition. This transition may be similar to some of the data from temperature-modulated DSC experiments showing a recrystallization at the start of the melt.[91–94] In both cases, some subtle changes in structure are sometimes detected at the start of melting. Following this transition, a material enters the terminal or melting region.

Depending on its strength, the heat set temperature can also be seen in DMA. While it is normally seen in either a TMA or a constant gauge length (CGL) experiment, it will sometimes appear as either a sharp drop in storage modulus (E') or an abrupt change in probe position. Heat set is the temperature at which some strain or distortion is induced into polymeric fibers to change its properties, such as to prevent a nylon rug from feeling like a fishing line. Since heating above this temperature will erase the texture, and polyesters must be heated above the T_g to dye them, it is of critical importance to the fabric industry. Many final properties of polymeric products depend on changes induced in processing.[95,96]

4.1.4 The Terminal Region

On continued heating, the melting point, T_m, is reached. The melting point is where the free volume has increased

Figure 14 Molecular weight and flow: the terminal zone or melting region follows the rubbery plateau and is sensitive to the M_w of the polymer. (Reproduced with permission of Taylor & Francis Group LLC.)

so that the chains can slide past each other and the material flows. This is also called the *terminal region*. In the molten state, this ability to flow is dependent on the molecular weight of the polymer (Figure 14). The melt of a polymer material will often show changes in temperature of melting, width of the melting peak, and enthalpy as the material changes[97,98] resulting from changes in the polymer molecular weight and crystallinity.

Degradation, polymer structure, and environmental effects all influence the changes that occur. Polymers that degrade by cross-linking will look very different from those that exhibit chain scission. Very highly cross-linked polymers will not melt, as they are unable to flow.

The study of polymer melts and especially their elasticity was one of the areas that drove the development of commercial DMA instruments. Although a decrease in the melt viscosity is seen with temperature increases, DMA is most commonly used to measure the frequency dependence of the molten polymer and its elasticity. The latter property, especially when expressed as the normal forces, is very important in polymer processing.

Recently, methods have been developed to hold and handle powders in the DMA. These Material Pockets allow the holding of materials that can support their own weight. This allows the measurement of the glass transition not measurable in substances such as amorphous lactose, protein excipient mixtures, and amorphous drugs.

4.1.5 *Frequency Dependences in Transition Studies*

The choice of a testing frequency or its effect on the resulting data must be addressed. A short discussion of how frequencies are chosen and how they affect the measurement of transitions is in order. Considering that higher frequencies induce more elastic like behavior, there is some concern that a material will act stiffer than it really is if the test frequency is chosen to be too high. Frequencies for testing are normally chosen by one of three methods. The most scientific method would be to use the frequency of the stress or strain to which the material is exposed in the real world. However, this is often outside the range of the available instrumentation. In some cases, the test method or the industry standard sets a certain frequency and this frequency is used. Ideally, a standard method such as this is chosen so that the data collected on various commercial instruments can be shown to be compatible. Some of the American Society for Testing and Materials (ASTM) methods for DMA are listed in Table 1. Many industries have their own standards, so it is important to know whether the data are expected to match a Mil-spec, an ASTM standard, or a specific industrial test. Finally, one can arbitrarily pick a frequency. This is done more often than not, and 1 Hz and 10 rad s^{-1} are often used. As long as the data are obtained under the proper conditions, they can be compared to highlight material differences. This requires that frequency, stresses, and the thermal program be the same for all samples in the data set.

Lowering the frequency shifts the temperature of a transition to a lower temperature (Figure 15). At one time, it was suggested that multiple frequencies could be used and T_g should then be determined by extrapolation to

Figure 15 Effect of frequency on transitions: the dependence of T_g in polymethyl methacrylate (PMMA) on frequency.

0 Hz. This has not been accepted, but multiple frequency runs are quite useful. Different types of transitions also have different frequency dependences; McCrum et al.[33] have listed many of these. If one looks at the slope of the temperature dependence of transitions against frequency, one sees that in many cases the primary transitions such as T_m and T_g have a different dependence on frequency than the lower temperature transitions. In fact, the activation energies are different for α, β, and γ transitions because of the different motions required and the transitions can be sorted by this approach.[1–3,10,51] Running a sample at two or three frequencies in a temperature scan tells you about the type of transition measured and also gives you an estimate of the degree of shrift per decade.[15] The frequency scan will be discussed further below.

Frequency scans are often done on these materials to generate master curves using the Williams–Landel–Ferry (WLF) equation.[9] A material will be isothermally scanned across a selected frequency range, normally the full range of the instrument, and then heated to another temperature where the process repeats. One temperature is selected as the reference temperature and the data is shifted around it. The resulting master curve allows estimation of E' and tan δ over a very wide temperature range. An example is seen in Figure 16. The WLF time–temperature superposition makes some specific assumptions and these need to be followed if the data is to be useful.[1,9,15] Superposition can also be preformed with stress[99] as well as using other models.[100,101]

4.2 Polymer Melts and Solutions

A fluid or polymer melt responds to strain rate rather than to the amount of stress applied. The viscosity is one of the main reasons why frequency scans are run. As the stress–strain curves and the creep recovery runs show, viscoelastic materials exhibit some degree of flow or unrecoverable deformation. The effect is strongest in melts and liquids in which frequency versus viscosity plots are the major application of DMA.

Figure 17 shows a frequency scan on a viscoelastic material. In this example, the sample is a rubber above T_g in three-point bending, but the trends and principles apply to both solids and melts. The storage modulus and complex viscosity are plotted on logarithmic scales against log (frequency). In analyzing the frequency scans, trends in the data are more significant than specific peaks or transitions.

Starting with the viscosity curve, η^*, a fairly flat region appears at low frequency, called the *zero shear plateau*.[102] This is where the polymer exhibits Newtonian behavior and its viscosity is dependent on molecular weight, and not the strain rate. The viscosity of this plateau has been shown to be related experimentally to the molecular weight for a Newtonian fluid (Equation 22):

$$\eta_0 \propto cM_v^1 \tag{22}$$

For cases where the molecular weight, M_v, is less than the entanglement molecular weight, M_e and for cases where M_v is greater than M_e (Equation 23)

$$\eta_0 \propto cM_v^{3,4} \tag{23}$$

where η_0 is the viscosity of the initial Newtonian plateau, c is a material constant, and M_v is the viscosity-average molecular weight. This relationship can be written in

Figure 16 The time–temperature–superposition (TTS) of a rubber is shown. The insert shows the plot of shift constants in (a) and the Cole-Cole Plot in (b).

general terms, replacing the exponential term with the Mark–Houwink constant, a. Equation (23) can be used as a method of approximating the molecular weight of a polymer. The value obtained is closest to the viscosity-average molecular weight obtained by osmometry.[103] In comparison with the weight-average data obtained by gel permeation chromatography (GPC), the viscosity-average molecular weight would be between the number-average and weight-average molecular weights, but closer to the latter.[104] This was originally developed for steady shear viscosity but also applies to complex viscosity.

The relationship between steady shear and complex viscosity is fairly well established. Cox and Merz[105,106] found that an empirical relationship exists between complex viscosity and steady shear viscosity when the shear rates are the same. The Cox–Merz rule is stated as (Equation 24):

$$|\eta(\omega)| = \eta(\dot{\gamma})|_{\dot{\gamma}=\omega} \tag{24}$$

where η is the constant-shear viscosity, η^* is the complex viscosity, ω the frequency of the dynamic test, and $d\gamma/dt$ the shear rate of the constant-shear test. This rule of

Figure 17 An example of a frequency scan showing the change in a material's behavior as the frequency varies. Low frequencies allow the material time to relax and respond, and hence flow dominates. High frequencies do not allow relaxation and elastic behavior dominates. (Reproduced with permission of Taylor & Francis Group LLC.)

Figure 18 The crossover point between either E' and E'' or between E' and η^* for a material corresponding to the relative molecular weight and molecular weight distribution. (Reproduced with permission of Taylor & Francis Group LLC.)

thumb seems to hold for most materials to within about ±10%. Another approach is the Gleissele[107] mirror relationship, which states (Equation 25):

$$\eta\dot{\gamma} = \eta^{+}(t)|_{t=1/\dot{\gamma}} \tag{25}$$

when $\eta^{+}(t)$ is the limiting value of the viscosity as the shear rate, $\dot{\gamma}$, approaches zero.

The low-frequency range is where viscous or liquid like behavior predominates. If a material is stressed over long enough times, some flow occurs. As time is the inverse of frequency, this means that materials are expected to flow more at low frequency. As the frequency increases, the material will act in a more and more elastic fashion. Silly Putty, the children's toy, shows this clearly. At low frequency, Silly Putty flows like a liquid, whereas at high frequency it bounces like a rubber ball.

This behavior is also similar to what happens with temperature changes. A polymer becomes softer and more fluid as it is heated and it goes through transitions that increase the available space for molecular motions. Over long enough time periods, or small enough frequencies, similar changes occur. Hence one can move a polymer across a transition by changing the frequency. This relationship is also expressed as the idea of time–temperature equivalence.[108] Often stated as low-temperature equivalent to short times or high frequency, it is a fundamental rule of thumb in understanding polymer behavior.

As the frequency is increased in a frequency scan, the Newtonian region is exceeded and a new relationship develops between the rate of strain, or the frequency, and the viscosity of the material. This region is often called the *power-law zone* and can be modeled by Equation (26):

$$\eta^* \approx \eta(\dot{\gamma}) = \mathrm{c}\dot{\gamma}^{n-1} \tag{26}$$

where η^* is the complex viscosity, $\dot{\gamma}$ is the shear rate, and the exponent term n is determined by the fit of the data. It can also be written as Equation (27):

$$\sigma \approx \eta(\dot{\gamma}) = c\dot{\gamma}^{n} \tag{27}$$

where σ is the stress and η is the viscosity. The exponential relationship is why the viscosity versus frequency plot is traditionally plotted on a logarithmic scale. With modern curve-fitting programs, the use of log–log plots has declined and is rather anachronistic. The power-law region of polymers shows shear thickening or thinning behavior. This is also the region in which the E'–η^* or the E'–E'' crossover point is found. As the frequency increases and shear thinning occurs, the viscosity (η^*) decreases. At the same time, increasing the frequency increases the elasticity (E'). This is shown in Figure 18. The E'–η^* crossover point is used as an indicator of the molecular weight and molecular weight distribution.[109] Changes in its position are used as a quick method of detecting changes in the molecular weight and distribution of a material. After the power-law region, another plateau is seen, the infinite shear plateau.

This second Newtonian region corresponds to where the shear rate is so high that the polymer no longer shows a response to increases in the shear rate. At the very high shear rates associated with this region, the polymer chains are no longer entangled. This region is seldom seen in DMA experiments and is usually avoided in use because of the damage done to the chains. It can be reached in commercial extruders and causes degradation of the polymer, which causes the poorer properties associated with regrind.

As the curve in Figure 18 shows, the modulus also varies as a function of the frequency. A material exhibits more elastic-like behavior as the testing frequency increases,

Figure 19 Comparison of a modulus scan taken by scanning at various frequencies and by varying the temperature. This relationship is called *time–temperature equivalency* and is discussed later. (Reproduced with permission of Taylor & Francis Group LLC.)

and the storage modulus tends to slope upward toward higher frequency. The change in storage modulus with frequency depends on the transitions involved. Above T_g, the storage modulus tends to be fairly flat with a slight increase with increasing frequency as it is on the rubbery plateau. The change in the region of a transition is greater. If one can generate a modulus scan over a wide enough frequency range (Figure 19a and b), the plot of storage modulus versus frequency appears like the reverse of a temperature scan. The same time–temperature equivalence as discussed above also applies to modulus, in addition to compliance, tan δ, and other properties.

The frequency scan is used for several purposes, which will be discussed in this section. One very important use that is very straightforward is to survey the material's response over various shear rates. This is important because many materials are used under different conditions. For example, adhesives, whether tape, Band-Aids, or hot melts are normally applied under conditions of low frequency and this property is referred to as *tack*. When they are removed, the removal often occurs under conditions of high frequency called *peel*. Different properties are required in these regimes and to optimize one property may require chemical changes that harm the other. Similarly, changes in polymer structure can show these kinds of differences in the frequency scan. For example, branching affects different frequencies.[36]

For example, in a tape adhesive, sufficient flow under pressure at low frequency is desired to fill the pores of the material to obtain a good mechanical bond. When the laminate is later subjected to peel, the material needs to be very elastic so that it will not pull out of the pores (this is a very simplified version of adhesion; a detailed discussion can be found elsewhere).[110,111] The frequency scan allows the measurement of these properties in one scan, thereby ensuring that tuning one property does not degrade another. This type of testing is not limited to adhesives, as many materials see multiple frequencies in actual use. Viscosity versus frequency plots are used extensively to study how changes in polymer structure or formulations affect the behavior of the melt. Often, changes in materials, especially in uncured thermosetting resins and molten materials, affect a limited frequency range and testing at a specific frequency can miss the problem.

It should be noted that when a solid material is scanned across a frequency range, there are some conditions where the material–instrument system acts like a guitar string and begins to resonate when certain frequencies are reached. These frequencies are either the natural resonance frequency of the sample–instrument system or one of its harmonics. This is shown in Figure 20. Under this set of experimental conditions, the sample–instrument system is oscillating like a guitar string and the desired information about the sample is obscured. Since there is no way to change this resonance behavior, as it is a function of the system (in a free resonance analyzer, this effect is necessary), it is required to redesign the experiment by changing the sample dimensions or geometry to escape the problem. Using a sample with very different dimensions, which changes the mass or changing from extension to three-point bending

Figure 20 Free resonance occurring during a frequency scan. (With permissions from PerkinElmer Life and Analytical Sciences, Shelton, CT.)

geometry changes the natural oscillation frequency of the sample and hopefully solves this problem.

4.3 Thermoset Curing

The ability of DMA to give viscosity and modulus values for each point in a temperature scan allows the estimation of kinetic behavior as a function of viscosity. This has the advantage of describing how fluid the material is at any given time, so as to determine the best time to apply pressure, what design of tooling to use, and when the material can be removed from the mold. The simplest way to analyze a resin system is to run a plain temperature ramp from ambient to some elevated temperature.[112–116] This ''cure profile'' allows the collection of several vital pieces of information as shown in Figure 21.

4.3.1 Cure Studies in the Dynamic Mechanical Analysis

Before analyzing the cure in Figure 21 in more detail, it should be mentioned that in curing studies all three types of commercial DMA instruments are used. The shape of curve and the temperature of events follow the same pattern. The values for viscosity and modulus often differ greatly. Both types of forced resonance DMA instruments also use samples impregnated into fabrics in techniques that are referred to as *torsional braid*. There are some problems with this technique, as temperature increases it will cause an apparent curing of nondrying oils because thermal expansion increases friction. However, the ''soaking of resin into a shoelace'', as this technique has been called, allows one to handle difficult specimens under conditions where the pure resin is impossible to run in bulk (owing to viscosity or evolved volatiles). Composite materials such as graphite–epoxy composites are sometimes studied in industrial situations as the composite rather than the ''neat'' or pure resin because of the concern that the kinetics may be significantly different. In terms of ease of handling the sample, the composite is often easier to work with.

Another special area of concern is paints and coatings[117,118] where the material is used in a thin layer. This can be addressed experimentally by either a braid as above or coating the material on a thin sheet of metal. The metal is often run first and its scan subtracted from the coated sheet's scan to leave only the scan of the coating. This is also done with thin films and adhesive coatings.

A sample cure profile for a commercial two-part epoxy resin is shown in Figure 21. From this scan, it is possible to determine the minimum viscosity (η^*_{min}), the time to η^*_{min} and the length of time it stays there, the onset of cure, the point of gelation where the material changes from a viscous liquid to a viscoelastic solid, and the beginning of vitrification. The minimum viscosity is seen in the complex viscosity curve, and it is where the resin viscosity is the lowest. The minimum viscosity of a given resin is determined by its chemistry, the previous heat history of the resin, the rate at which the temperature is increased, and the amount of stress or stain applied. Increasing the rate of the temperature ramp is known to decrease the η^*_{min}, the time to η^*_{min}, and the gel time. Not only the resin becomes softer soon but also cures faster. The degree of flow limits the type of mold design and when and how much pressure can be applied to the sample. The time spent at the minimum viscosity plateau is the result of a competitive relationship between the material's softening or melting, as it heats, and its rate of curing. At some point, the material begins to cure faster than it softens, and that is where the viscosity starts to increase.

As the viscosity begins to climb, an inversion is seen of the E'' and E' values as the material becomes more solid like. This crossover point also corresponds to where the tan $\delta = 1$ (since $E' = E''$ at the crossover). This is taken to be the gel point,[15,19,22,73,99–101,119–164] where the cross-links have progressed to forming an

''infinitely'' long network across the specimen. At this point, the sample will no longer dissolve in the solvent. Although the gel point correlates fairly often with this crossover, it does not always do so. For example, for low initiator levels in chain addition thermosets, the gel point precedes the modulus crossover.[122] A temperature dependence for the presence of the crossover has also been reported.[112–116] In some cases where powder compacts and melts before curing, there may be several crossovers.[123] Then, the one following the η^*_{min} is usually the one of interest. Some researchers[124–126] believe that the true gel point is best detected by measuring the frequency dependence of the crossover point. This is done either by multiple runs at different frequencies or by multiplexing frequencies during the cure. At the gel point, the frequency dependence disappears.[126] The value is usually only a few degrees different from that obtained in a normal scan. During this rapid climb of viscosity in the cure, the slope for η^* increase can be used to calculate an estimated E_a (activation energy).[127] This will be discussed in the subsequent text, but the fact that the slope of the curve here is a function of E_a is important. Above the gel temperature, some workers estimate the molecular weight, M_c, between cross-links according to Equation (28):

$$G' = \frac{RT\rho}{M_c} \tag{28}$$

where R is the gas constant, T is the temperature in kelvins, and ρ is the density. At some point the curve begins to level off and this is often taken as the vitrification point, T_{vf}.

The vitrification point is where the cure rate slows because the material has become so viscous that the bulk reaction has stopped. At this point, the rate of cure slows significantly. The apparent T_{vf}, however, is not always real: any analyzer has an upper force limit. When that force limit is reached, the 'topping out' of the analyzer can pass as the T_{vf}. Use of a combined technique such as DMA/DEA (DEA is dielectric analysis, where an oscillating electrical signal is applied to a sample; from this signal, the ion mobility can be calculated, which is then converted to a viscosity (see McCrum et al.[20] for details; DEA will measure up to significantly higher viscosities than DMA) to see the higher viscosities or the removal of a sample from a parallel plate and sectioning it into a flexure beam is often necessary to see the true vitrification point. A reaction can also completely cure without vitrifying and will level off in the same way. One should be aware that reaching vitrification or complete cure too quickly could be as bad as reaching it too slowly. Often, an overly aggressive cure cycle will lead to a weaker material, as it does not allow for as much network development, but gives a series of hard (highly cross-linked) areas among softer (lightly cross-linked) areas.

On the way to vitrification, an important value is 10^6 Pa s. This is the viscosity of bitumen[128] and is often used as a rule of thumb for which a material is stiff enough to support its own weight. This is a rather arbitrary point, but is chosen to allow the removal of materials from a mold and the cure is then continued as a postcure step. As will be seen below, the postcure is often a vital part of the curing process.

The cure profile is both a good predictor of performance and a sensitive probe of processing conditions. A final note on cure profiles is that a volume change occurs during the cure.[129] This shrinkage of the resin is important and can be studied by monitoring the probe position of some DMA instruments and also by TMA and dilatometry.

4.3.2 *Photocuring*

A photocure in a DMA instrument is run by applying a UV light source to a sample that is held at a specific temperature or subjected to a specific thermal cycle.[130–132] Photocuring is done for dental resin, contact adhesives, and contact lenses. UV exposure studies are also run on cured and thermoplastic samples by the same techniques as used in photocuring to study UV degradation. The cure profile of a photocure is very similar to that of a cake or epoxy cement. The same analysis is used and the same types of kinetics are developed as for thermal curing studies. The only difference is that the cure is now driven by light rather than temperature.

While the PerkinElmer DMA-7e had been successfully adapted[133] to use quartz fixtures, newer instruments like the PerkinElmer DMA 8000 are now available with UV curing accessory as complete packages. Besides photocuring, these instruments can also be used for degradation studies under high-intensity UV or visible light.[1]

4.3.3 *Modeling Cure Cycles*

The above discussions are based on using a simple temperature ramp to see how a material responds to heating. In actual use, many thermosets are actually cured using more complex cure cycles to optimize the trade-off between the processing time and the final product's properties.[134,135] The use of two-stage cure cycles is known to develop stronger laminates in the aerospace industry. Exceptionally thick laminates often also require multiple stage cycles in order to develop strength without porosity. As thermosets shrink on curing,

careful development of a proper cure cycle to prevent or minimize internal voids is necessary.

One reason for the use of multistage cures is to drive reactions to completion. Another is to extend the minimum viscosity range to allow greater control in forming or shaping of the material. The development of a cure cycle with multiple ramps and holds would be very expensive if done with full-sized parts in production facilities. The use of DMA gives a faster and cheaper way of optimizing the cure cycle to generate the most efficient and tolerant processing conditions.

4.3.4 *Isothermal Curing Studies*

Often curing is done at a constant temperature for a period of time. This is how the data needed for the kinetic models discussed in the next section are normally collected. It is also how rubber samples are cross-linked, how initiated reactions are run, and how bulk polymerizations are performed. Industrially, continuous processes, as opposed to batch, often require an isothermal approach. UV light and other forms of nonthermal initiation also use isothermal studies for examining the cure at a constant temperature.

4.3.5 *Curing Kinetics by Dynamic Mechanical Analysis*

Several approaches have been developed to studying the chemorheology of thermosetting systems. Halley and MacKay[136] recently reviewed chemorheology and the more common kinetic models. A fundamental method is the WLF model,[137] which looks at the variation of T_g with degree of cure. This has been used and modified extensively.[138,139] A common empirical model for curing has been proposed by Roller et al.[140–145] In the latter approach, samples of the thermoset are run isothermally as described above and the viscosity versus time data are collected. This is plotted as log η^* versus time in seconds, where a change in slope is apparent in the curve. This break in the data indicates that the sample is approaching the gel time. From these curves, the initial viscosity, η_0, and the apparent kinetic factor, k, can be determined. By plotting log (viscosity) versus time for each isothermal run, the slope, k, and the viscosity at $t = 0$ are apparent. The initial viscosity and k can be expressed according to Equations (29) and (30):

$$\eta_0 = \eta_\infty e^{\Delta E_\eta / RT} \tag{29}$$

$$k = k_\infty e^{\Delta E_k / RT} \tag{30}$$

Combining these allows one to set up the equation for viscosity under isothermal conditions (Equation 31):

$$\ln \eta(t) = \ln \eta_\infty + \frac{\Delta E_\eta}{RT} + t k_\infty e^{\Delta E_k / RT} \tag{31}$$

By replacing the last term with an expression that treats temperature as a function of time, the equation becomes Equation (32):

$$\ln \eta(T, t) = \ln \eta_\infty + \frac{\Delta E_\eta}{RT} + \int_0^t k_\infty e^{\Delta E_k / RT}\, dt \tag{32}$$

This equation can be used to describe viscosity–time profiles for any run where the temperature can be expressed as a function of time. The activation energies can now be calculated. The plots of the natural logarithm of the initial viscosity (determined above) versus $1/T$ and the natural logarithm of the apparent rate constant, k, versus $1/T$ are used to give the activation energies, ΔE_η and ΔE_k. Comparison of these values of k and ΔE with those calculated by DSC shows that this model gives larger values.[117,118] The DSC data are faster to obtain, but they do not include the needed viscosity information.

Several corrections have been proposed, addressing different orders of reaction[146] (the above assumes first order) and modifications to the equations.[147,148] Many of these adjustments are reported in Roller's 1986 review[149] of curing kinetics. It is noted that these equations do not work well above the gel temperature. This same equation has been used to predict the degradation of properties in thermoplastics successfully.[150]

4.3.6 *Mapping Thermoset Behavior: the Gillham–Enns Diagram*

Another approach to attempt to understanding fully the behavior of a thermoset was developed by Gillham et al.[151–157] and is analogous to the phase diagrams used by metallurgists. The time–temperature–transformation (TTT) diagram or the Gillham–Enns diagram (after its creators) is used to track the effects of temperature and time on the physical state of a thermosetting material. Figure 22 shows an example. Running isothermal studies of a resin at various temperatures and recording the changes as a function of time can do this. One has to choose values for the various regions and Gillham et al. have done an excellent job of detailing how one picks T_g, the glass, the gel, the rubbery, and the charring regions.[158,159] These diagrams are also generated from DSC data,[160] and several variants,[161,162] such as the continuous heating transformation and conversion–temperature–property diagrams, have been

Figure 22 The Gillham–Enns or TTT diagram. (Reprinted from B. Bilyeu's Ph.D. thesis and used with his permission.)

reported. Surprisingly easy to do, although rather slow, they have not yet been accepted in the industry despite their obvious utility. A review[163] summarizes the approach, which has details on these and the continuous heating variant.

4.4 Testing Environmental Effects

One of the major advances recently in DMA is the ability to test in both solution and controlled humidity environments. Many materials' properties change on exposure to solvents and relative humidity and this is a problem for materials in use. The ability to run samples in a solvent bath or in a humidity chamber and to see how these materials change is an important addition to any testing regimen.

4.4.1 Immersion Studies

Figure 23 shows a DMA run on a sample of spaghetti run in a fluid bath with water as the solvent. As the water heats, the spaghetti softens. While this experiment does not take it to *al dente*, it makes a nice example of the approach. In most cases, the solvent acts to plasticize the material as time and temperature increase. Studies of materials in solution are numerous and include

Figure 23 The effect of immersion into warm water on a pasta strand is shown. Modulus decreases and tan delta increases as soak time and temperature increase).

Figure 24 The affect of humidity on a sample of tea leaves run in a metallic Material Pocket shows the decrease in modulus as moisture is absorbed by the tea.

polystyrene resistance to oil,[164] coaxially coated fibers,[165] polymers,[166] aerospace materials[167] as well as dental materials, polyamide composites, epoxy films, and fishing lines. Many biomedical devices are also tested this way.

4.4.2 Humidity Studies

Anyone working with materials like paper, nylon fibers, or sugars is well aware of the effect that moisture levels changes have on T_g and the modulus values. Water is known to act as a plasticizer in polymers and most studies on the effect of water have involved soaking the material in a solution or subjecting it to a humidity chamber and then running it under dry gas. Running the samples in humidity directly allows you to see how water changes the modulus as it is absorbed as well as the effects of the relative humidity level on final properties.

Examples of the effect of humidity are shown in Figure 24. In the first case, samples of dry tea leaves were loaded into a material pocket and allowed to equilibrate at 75% RH. It was then temperature scanned to measure T_g. A second sample was tested at 40% RH. The second example shows the change in the sucrose T_g as a function of humidity. The third example shows a nylon fishing line. A range of materials have been reported in the literature including cellulose films,[168] sunflower protein isolate,[169] Nafion™ 117 films,[170] polyesters,[170] leather,[171] and polyurethanes.[172]

ACKNOWLEDGMENTS

Field-flow fractionation (FFF) was conceived by J. Calvin Giddings in 1966 as a separation and characterization method for macromolecules, colloids, and particulates. Like chromatography, sample migration is caused by differential interaction with a field acting along an axis orthogonal to that of the transport liquid. Unlike chromatography, where separation is achieved by solutes partitioning between mobile and stationary phases, separation in FFF arises from the distribution of sample components in fluid laminae flowing at different velocities in a single phase. The different flow velocities, described by a parabolic profile, arise from the high aspect ratio of the FFF channel. Different types of fields can be used in FFF as long as they interact with some physicochemical property of the sample. The FFF channel design makes it highly suited for analyses of fragile aggregates, high-molecular-weight polymers, and gels. In comparison with packed columns, shear rates in the channel and the probability of plugging the channel are low. The ability of thermal FFF to differentiate polymers and latexes of different bulk and surface composition is unique among currently used separation techniques. The FFF family of techniques can provide a great deal of information about the sample but an initial time investment is often required for methods development.

In this article, the fundamental mechanism of FFF is shown at play in the separation and characterization of polymers and rubbers by the two techniques par excellence in this field: flow FFF and thermal FFF.

1 INTRODUCTION

FFF is a separation method conceived by J. Calvin Giddings in 1966.[1] It is particularly suitable for macromolecular, colloidal and diverse particulate materials extending from a few hundred[2,3] to 10^{18} Da.[4] It is an elution technique and is often referred to as a chromatography-like technique. In chromatography, the solute's rate of migration is determined by its partitioning between a mobile phase and a stationary phase in a column. In FFF, an externally applied field induces selective distribution of solutes in fluid laminae flowing at different velocities in a single phase inside a channel. The difference in the type of forces used in chromatography and in FFF defines the range of applicability of the techniques. While forces in chromatography are localized at interfaces and very selective, those used in FFF and electrophoresis are more diffuse and weaker. Consequently, the mass transport phenomena occurring in a chromatographic technique, such as high-performance liquid chromatography (HPLC), tend to be slower as the solute molecular weight increases. When the molecule's energy of interaction with the interface is significantly greater than the

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

thermal energy kT, adsorption becomes irreversible.[5] However, even before irreversible adsorption appears, structural disruption and denaturation of the macromolecular component may occur because of the strong shear forces present in the irregular flow in the tightly packed chromatography column.[6] By contrast, the FFF separation is carried out in the absence of a stationary phase within an open channel. This channel is obtained by removing a geometrical portion from a Teflon, Mylar, or polyimide spacer and then clamping the spacer between two flat parallel plates. As shown in Figure 1, the removed section of the channel is a parallelepiped with tapered ends that facilitate the flow of liquid and sample in and out of the channel. The most commonly used channel dimensions are 27–87 cm in length L, 1–2 cm in breadth b and 0.0075–0.05 cm in thickness w. Because of the very high aspect ratio of the FFF channel and the frictional drag at the walls, the velocity of a liquid carrier moving in the longitudinal direction has a parabolic profile with a maximum in the center and minima, virtually zero, at the walls. In the normal mode of operation, the field applied perpendicular to the flow direction drives sample components toward one wall, referred to as accumulation wall,[7] with a velocity determined by the particle–field interaction. This field-induced displacement, optimized in the absence of longitudinal flow, is always counteracted by the diffusive flux that originates from the concentration gradient across the channel. The combination of these opposing effects results in a nonuniform distribution of components across the channel, those with a higher rate of back-diffusion being driven further away from the accumulation wall than those with a lower diffusion rate. Because of the parabolic flow velocity profile in the channel, the faster-diffusing component C shown in Figure 1 will be displaced along the channel more rapidly than component B, which has a lower diffusivity. The output signal, collected by a detector sensitive to some solute property, will thus register the elution profile of distinct peaks.

The normal mode of operation described above is the one mostly used for polymer separations because of the molecular size/weight range of these particular materials. Another retention mechanism, steric FFF,[8,9] comes into play when the component size is significant relatively to the channel thickness. This is generally the case for particle dimensions higher than 1 μm. The solute elution velocity is determined, in this case, by the extension of component particles into the flow. Larger particles extend into regions of faster streamlines because of steric exclusion from the accumulation wall and elute earlier than smaller particles. The retention order in this mode is reverse of that in the normal mode of operation.

Given the precise channel geometry and the flow profile that may be described mathematically, retention

Figure 1 Schematic diagram of a typical FFF channel and the normal mode FFF separation mechanism. (Reproduced from L.F. Kesner, J.C. Giddings, *High Performance Liquid Chromatography*, eds. P.R. Brown, R.A. Hartwick, Chapter 15, 1989. Copyright © 1989, John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

in FFF may be accurately calculated in theory and related to various solute physicochemical properties.[10,11] The particular sample property controlling retention depends on the type of the applied field. The use of different fields has generated a number of FFF techniques, such as sedimentation field-flow fractionation (SdFFF)[12] when a centrifugal force is used to induce retention, flow field-flow fractionation (FlFFF)[13] when the field is established by a transverse or crossflow of liquid, thermal field-flow fractionation (ThFFF)[14] when a thermal gradient is used, and electrical field-flow fractionation (ElFFF)[15] when a potential gradient is applied to electrically charged solutes.

FFF is particularly suitable for the separation of macromolecular samples and suspended colloidal particles of various origins because of the minimal surface area of the channel compared with the total surface area of a packed chromatographic column (10^7 cm^2).[16] For this reason, adsorption phenomena are greatly reduced in FFF. The driving force may be accurately adjusted to yield the desired levels of retention without the need to change the column as in chromatography and sample distribution between zones is very fast because no phase boundaries must be crossed. A rich literature is available for a great number of applications from colloids of environmental origin[17] to bacteria and viruses.[18]

2 THEORY

The theory of retention discussed in this section is developed for point particles at infinite dilution, that

is, for species with negligible size with respect to the channel dimensions, particularly its thickness. When this assumption is not satisfied corrections must be made to account for the particle size. One such correction is considered in the retention model for steric FFF.

2.1 Basic Theory of Retention

Let us consider the space between two parallel plates and a field applied orthogonal to them in the x-direction (measured across the channel thickness from the accumulation wall). Under the effect of the field alone, component particles are displaced with a velocity U. The particles' motions give rise to a field-induced flux Uc defined as the number of particles per unit cross-sectional area per unit time directed toward the accumulation wall, that is in the negative x-direction. The field-induced displacement is, however, counteracted by a diffusive flux proportional to the concentration gradient $\mathrm{d}c/\mathrm{d}x$ through the component's diffusion coefficient D and directed in the positive x-axis direction. The mass transport across the channel determines a net flux J_x given by Equation (1):

$$J_x = Uc - D\frac{\mathrm{d}c}{\mathrm{d}x} \tag{1}$$

The concentration profile across the channel thickness reaches a steady state when the field-induced and diffusive fluxes are at equilibrium. At this point the net flux is equal to zero. Equation (1) is integrated and solved, assuming constant U and D, to give an equation that describes the steady state concentration profile (Equation 2):

$$\frac{c(x)}{c_0} = \exp\left(-\frac{|U|}{D}x\right. \tag{2}$$

where c_0 is the concentration at the accumulation wall, x is the distance from the wall, and $|U|$ is negative for consistency with the coordinate system. Concentration decreases exponentially from the accumulation wall. Since it may be shown that an exponential distribution behaves as a much thinner layer positioned at a characteristic height ℓ, Equation (2) may be rewritten as Equation (3):

$$\frac{c(x)}{c_0} = \exp\ -\frac{x}{\ell} \tag{3}$$

where (Equation 4)

$$\ell = \frac{D}{|U|} \tag{4}$$

The mean layer thickness ℓ is a measure of the average distance of a sample component from the accumulation wall. It is apparent from Equation (4) that ℓ depends on the opposing effects of the field that acts to compress the solute layer and the diffusion process that broadens it. The quantity ℓ is frequently expressed in the dimensionless form shown in Equation (5):

$$\lambda = \frac{\ell}{w} = \frac{D}{|U|w} \tag{5}$$

where w is the channel thickness and λ is the retention parameter basic to FFF equations. Since λ may be shown to be dependent on the field strength and on a sample–field interaction constant, each component will have a characteristic λ value.

After the formation of the steady-state zone, a stream of liquid is allowed to flow along the longitudinal axis of the channel. Component particles are then carried downstream with an average velocity that depends on the region where they are found. The sample distribution at this point assumes a Gaussian distribution in the longitudinal direction because of the free diffusive motion of component molecules between regions of different velocities across the channel. The elution time will then be different for different components and may be used to measure the sample elution velocity once the channel void volume is known. Elution time, however, is not the most universal parameter defining the behavior of a species migrating along a chromatographic column or an FFF channel since it always depends on the average fluid velocity. The dimensionless retention ratio R, defined as the ratio of component migration velocity v_p to the mean fluid velocity $\langle v\rangle$ (Equation 6),

$$R = \frac{v_\mathrm{p}}{\langle v\rangle} \tag{6}$$

is a more useful parameter. R is widely used in separation techniques as a measure of the retardation of the solute relative to the liquid carrier flow velocity. It is a more universal measure of retention than elution time and only depends on the field strength and on the particle property responding to the field, regardless of the flow velocity. It then frees the mathematical architecture from a variable. In the expression of R, the solute mean migration velocity is the average of the particle velocities expressed as $v_\mathrm{p} = \langle cv\rangle/\langle c\rangle$.[19] Inserting this expression into Equation (6), substituting the concentration term with Equation (3) and the parabolic function to calculate v, and using Equation (5), one obtains an expression for R whose solution is given by Equation (7):

$$R = 6\lambda\left(\coth\frac{1}{2\lambda} - 2\lambda\right. \tag{7}$$

Equation (7) is the basic retention equation in FFF. It shows that retention is solely dependent on λ, which is characteristic of each eluting species. Approximate forms of Equation (7) may be used for low λ values or high levels of retention. In particular, the approximation $R = 6\lambda$ has

an error of 20% at $R = 0.25$. The empirical relationship $R = 6(\lambda - 2\lambda^2)$ has the greater range of applicability with less than 10% error up to $R = 0.7$. The retention ratio may also be written as $R = t^0/t_r$ since $V = L/t_r$ and $\langle v \rangle = L/t^0$, where t^0 is the residence time of the eluent or of a nonretained component and t_r the average sample residence time or retention time.

In theory, any external field to which sample components are responsive may be used to induce selective retention and fractionation by FFF. The applied field determines the type of interaction and hence the sample property that will be measured. Besides FlFFF, ThFFF, SdFFF and ElFFF, the theoretical foundation has also been laid down for many less developed FFF techniques. One such technique uses a concentration gradient in a solvent mixture to establish a chemical potential gradient capable of driving solutes towards regions of lowest potential [concentration field-flow fractionation (CFFF)].[20] A nonuniform electric field that induces charge polarization may exert selective dielectrophoretic forces on component particles and generate fractionation.[21] Interesting applications are reported using a magnetic field.[22] Photophoretic FFF[23] is based on the transfer of momentum from a photon to a particle. An acoustic wave field[24] may induce retention selective to particle diameter in addition to other parameters.

The present discussion focuses on the FFF techniques that have been applied to polymer separations: FlFFF and ThFFF. These techniques have been extensively used for a great number of different samples. They are the FFF techniques par excellence for polymer fractionation. ElFFF has shown its potential only with a new channel design[25] and may prove to be very useful for the characterization of charged polymers.

In his investigations on the theory of Brownian motion, Einstein[26] showed that in a system of point particles at infinite dilution, i.e. in the absence of flow perturbations due to the motion of one particle affecting another, the diffusion coefficient is inversely proportional to the friction coefficient (Equation 8):

$$D = \frac{kT}{f} \tag{8}$$

If D is replaced with the Einstein equation and the relationship for the field-induced velocity specific for FlFFF ($U = \dot{V}_c/Lb$) is used in Equation (5) one obtains

$$\lambda = \frac{kT}{f}\frac{V^0}{\dot{V}_c w^2} \tag{9}$$

In Equation (9), the relationship $V^0 = Lbw$ is also used to replace Lb with V^0/w. It is worth noting that Equation (9) depends on the friction coefficient f as well as on the instrumental parameters V^0 and w. This is not the case with SdFFF where both D and U depend inversely on f, which then cancels out in the ratio $D/|U|$. The dependence of the retention parameters λ and R on the friction coefficient in FlFFF is the key to obtaining solute physicochemical parameters from FFF measurements. More than a century before Einstein's work in this area, Stokes[27,28] found a quantitative relationship between the shape and the dimensions of a moving particle and its friction coefficient. For a spherical body of radius R_0 moving in a fluid of viscosity η he showed that the friction coefficient could be expressed by Equation (10):

$$f_0 = 6\pi\eta R_0 \tag{10}$$

Stokes' equation may be used to relate diffusion coefficient to particle dimensions. Correction factors that extend Stokes' relation to nonspherical particles were first introduced by Perrin[29] and Herzog et al.[30] for solids of revolution such as prolate (cigar-shaped) and oblate (disk-shaped) ellipsoids. They chose to express the departure of the actual friction coefficient f, for an ellipsoid with axes of symmetry of different length from the friction coefficient of a sphere of same volume f_0. They found a quantitative relation between f/f_0 and the ratio a/b of the semimajor axis a to the semiminor axis b. By combining Equations (8) and (10), Equation (11):

$$D_0 = \frac{kT}{6\pi\eta R_0} \tag{11}$$

is obtained. The Stokes–Einstein relation in Equation (11) is derived considering equivalent particle orientation which applies rigorously only to spherical bodies. The substitution of Equation (10) into Equation (9) gives the expression for λ in FlFFF (Equation 12):

$$\lambda = \frac{kT}{6\pi\eta R_0}\frac{V^0}{\dot{V}_c w^2} \tag{12}$$

which shows explicitly the effective size-based separation in normal-mode FlFFF where samples are retained proportionally to their hydrodynamic dimensions.

The expression for λ in ThFFF is derived using a conceptual procedure similar to that followed for FlFFF. The derivation of this expression is complicated, however, by the distortion of the parabolic flow profile due to changes of viscosity with temperature across the channel.[31,32] In 1856, Fick (and later Soret in 1859) showed that if a salt solution of uniform concentration in a tall container is heated at the top and cooled at the bottom, a flux of matter originates that increases the salt concentration at the cold end of the column. This effect, named after Soret, is known as thermal diffusion since it is clearly a diffusive effect occurring only in the presence of a thermal gradient. The equation of flux (Equation 1)

set for molar thermal and diffusive fluxes gives

$$J_x = -D\left(\frac{\mathrm{d}c}{\mathrm{d}x} + c\gamma\frac{\mathrm{d}T}{\mathrm{d}x}\right. \quad \left. - D_{\mathrm{T}}c\frac{\mathrm{d}T}{\mathrm{d}x}\right. \tag{13}$$

where D_{T} is the thermal diffusion coefficient and γ is the coefficient of thermal expansion. The solution for zero net flux at the steady state yields the retention parameter for ThFFF (Equation 14):

$$\lambda = \left. w \quad \frac{\alpha}{T} + \gamma \quad \frac{\mathrm{d}T}{\mathrm{d}x}\right.^{-1} \tag{14}$$

where α is the thermal diffusion factor equal to $D_{\mathrm{T}}T/D$.[33] Both α and $\mathrm{d}T/\mathrm{d}x$ depend on the local position x and thus on the temperature. The ordinary diffusion coefficient is strongly dependent on the temperature through the T/η term in Equation (11) where $1/\eta$ also increases with T. In the case of flexible-chain macromolecules, it must be borne in mind that, on polymer chemistry theoretical grounds, the molecular coil is expected to expand on increasing temperature as a consequence of the increased excluded volume. This property is treated in terms of the second virial coefficient.[34] The tendency of polymer hydrodynamic dimensions to increase with temperature is reported in light-scattering studies.[35] The local temperature gradient is not independent of T[31,32] but the dependence is relatively small. D_{T} is shown to depend on temperature[36] but to a smaller extent than the ordinary diffusion coefficient. In the standard theory of FFF, however, λ is generally used in an approximate form that is valid at high retention where the sample cloud is very close to the accumulation wall. The local values of $\mathrm{d}T/\mathrm{d}x$ and α may therefore be assumed to be the same as those at the cold wall.[37] The term γ becomes negligible[31] and λ may be rewritten as in Equation (15):

$$\lambda \approx \frac{T_{\mathrm{c}}}{\alpha w\left(\dfrac{\mathrm{d}T}{\mathrm{d}x}\right._{\mathrm{c}}} = \frac{D}{D_{\mathrm{T}}w\left(\dfrac{\mathrm{d}T}{\mathrm{d}x}\right._{\mathrm{c}}} \tag{15}$$

where $(\mathrm{d}T/\mathrm{d}x)_{\mathrm{c}}$ is the temperature gradient at the cold wall.

2.2 Molecular Weight Dependence on Physicochemical Parameters

Synthetic polymers are often flexible-chain molecules whose dimensions cannot be defined precisely and must be considered as average values of all the configurations that the molecules assume. In such a situation it is convenient to introduce a new parameter called the radius of gyration, R_{g}. It is found from polymer theory that molecular weight may be related to polymer molecular dimensions through this statistical parameter according to Equation (16):

$$R_{\mathrm{g}}^2 \propto \frac{M}{M_0} \tag{16}$$

where M is the molecular weight and M_0 is the molecular weight of the repeat unit (constant for synthetic homopolymers). The equivalent radius R_{e}, defined as the radius of an equivalent sphere having the same value of the friction and diffusion coefficients as the polymer, is a convenient parameter that is often used. Since it may be demonstrated that $R_{\mathrm{g}} \propto R_{\mathrm{e}}$,[34,38] equations dependent on R_{g} may be written in terms of the equivalent radius. For approximately spherical molecules, the volume of the molecule is linearly related to molecular weight. This may be expressed as Equation (17):

$$R_0 \propto M^{1/3} \tag{17}$$

where R_0 is the radius of a spherical particle. Globular proteins are an example of a real system that satisfies the model of a rigid spherical body. Even in such a simple case however, correction factors must be applied to Equation (17) to account for the hydration volume and deviation from the perfectly spherical symmetry. When the polymer molecule is a statistical chain that is allowed to meander randomly in a Brownian-like way with no forbidden physical volume, polymer theory shows that $\langle R_{\mathrm{g}}^2\rangle$ is proportional to the number of repeat units in the macromolecule chain given by $N = M/M_0$. It follows that the equivalent radius (or Stokes radius) is given by Equation (18):

$$R_{\mathrm{e}} \propto M^{1/2} \tag{18}$$

If the polymer chain is not allowed to self-cross, there is some space occupied by other polymer segments from which each segment is excluded. Polymer conformations are significantly affected by the excluded volume and the equivalent radius for a three-dimensional polymer chain model becomes (Equation 19):

$$R_{\mathrm{e}} \propto (M^{6/5})^{1/2} \tag{19}$$

Based on the model of the equivalent sphere (Stokes–Einstein relationship), Equation (11) may be applied to polymers in solution, and the diffusion coefficient, at a given temperature, may be related to molecular weight through the polymer equivalent dimensions R_{e} and the friction coefficient.[38,39] Substituting Equation (18) or (19) into Equation (11) and grouping together all the constants, we obtain Equation (20):

$$D = AM^{-b} \tag{20}$$

where A is constant for a given polymer type and b is an exponent that depends on the polymer conformation in

solution. The value of the exponent in Equation (18) is obtained on theoretical grounds, considering zero attractive or repulsive interactions between different polymer segments as well as between polymer molecules and the surrounding medium. It also assumes infinitely dilute systems of neutral, nonfree draining molecules with average spherical symmetry. A system under these conditions is defined as a Θ-system (theta-system) at Θ-temperature. Θ-conditions are set by the type of solvent (which determines the energy of interaction with the polymer molecules) and by the temperature. Generally, only one solvent behaves as a Θ-solvent for a given polymer type. Therefore, the theoretical value of the b exponent is always related to a specific polymer–solvent system at Θ-temperature. The excluded volume has a considerable swelling effect on flexible-chain molecules and on the dependence of particle size on molecular weight. The excluded volume effect is similar to and may also be thought of as that due to a good solvent or to a temperature higher than the Θ-temperature. By relating the diffusion coefficient and molecular weight at a given temperature, Equation (20) allows FFF-measured parameters to be correlated with the polymer molecular weight. Combining Equations (12) and (20), it appears that λ in FlFFF is inversely dependent on molecular weight, that is, the zone mean migration layer decreases as the polymer molecular weight increases (Equation 21):

$$\lambda = AM^{-b}\frac{V^0}{\dot{V}_c w^2} \tag{21}$$

A similar expression for ThFFF is complicated by the D_T term in Equation (15). In the classical theoretical treatment of FFF, D_T is considered independent of molecular weight,[37] as predicted and experimentally observed by some authors[40] (see section 5.1). Other authors,[41,42] however, report a molecular weight dependence of the thermal diffusion coefficient. Assuming that, at a given temperature, we have (Equation 22):

$$D_T = BM^{\beta} \tag{22}$$

and considering Equation (20) for the dependence of the ordinary diffusion coefficient on molecular weight, the overall contribution of molecular weight to λ in ThFFF is given by the D/D_T term as Equation (23):

$$\frac{D}{D_T} = \frac{A}{B}M^{-(b+\beta)} = \Phi M^{-n} \tag{23}$$

where $\Phi = A/B$ and $n = b + \beta$. The parameter Φ must be temperature dependent because of the dependence of D on temperature. Equation (23) substituted into Equation (15) yields a negative exponential correlation between λ and the molecular weight (Equation 24):

$$\lambda = \Phi M^{-n}\frac{1}{w\left(\dfrac{dT}{dx}\right)_c} \tag{24}$$

2.3 Conversion of a Fractogram to Molecular Weight Distribution

To obtain a meaningful molecular weight distribution of a polymer sample, it is necessary that elution occurs in the same mode (normal, steric, etc.) over the entire retention time interval with a monotonic function of some sample property. Transformation of a fractogram from a time-based function to a molecular weight function is readily accomplished but requires a correction to the amplitude to account for the nonlinear relationship between M and t_r. The mass abundance in a time interval δt_r, corresponding to $c(t_r)\dot{V}\delta t_r$, must equal the mass comprised in the corresponding molecular weight interval δM. Integrating the mass distribution $m(M)$ over that interval yields Equation (25):

$$m(M)\,\delta M = c(t_r)\dot{V}\delta t_r \tag{25}$$

where $c(t_r)$ is the detected sample concentration at time t_r and $\dot{V}$ is the volumetric channel flow rate. For $\delta t_r \to 0$, Equation (25) becomes Equation (26):

$$m(M) = c(t_r)\dot{V}\frac{dt_r}{dM} \tag{26}$$

The scale correction function dt_r/dM allows the conversion of the retention timescale to the molecular weight scale. For a normal-mode elution, the molecular weight distribution may be obtained in theory from first principles.[43]

2.4 Calibration Methods

It may be shown that the scale correction function depends on the constants A and b for FlFFF and Φ and n for ThFFF, through the dependence of λ on molecular weight. These constants may be found from theory and are available in literature for a wide number of polymer–solvent systems. However, it is common laboratory practice to obtain them through a calibration procedure with a set of well-characterized, narrowly distributed polymer standards whose molecular weights have been measured by some absolute technique such as light scattering, viscometry or osmometry. To obtain A and b values that can be transferred to an unknown polymer sample, calibration must be performed with standards of the same or similar composition as the unknown, in the same carrier liquid and at the same temperature. Constants A and b for the FlFFF analysis of

polymers are obtained from the intercept and slope of a plot of the measured $\log D$ versus $\log M$ (Equation 27):

$$\log D = \log A - b \log M \tag{27}$$

derived from Equation (20). The plot of $\log \lambda$ versus $\log M$ would also give these constants. A similar $\log \lambda \Delta T$ versus $\log M$ plot provides the constants Φ and n for the calibration in ThFFF. Gao and Chen[44] and Giddings[45] have shown the system transferability of the ThFFF calibration constants. A more detailed treatment of the "universal calibration" in ThFFF[46] also accounts for the change of the cold wall temperature on polymer retention and on the calibration constants. FFF constants allow a more universal calibration than size-exclusion chromatography (SEC) since they are derived from fundamental physical properties of the carrier liquid and of the polymer under investigation and do not depend on any system parameter. In contrast, calibration in SEC has no rigorous theoretical grounds; it is not valid for some pore structures[47] and it is therefore not system transferable. Moreover, it is still under evaluation for some types of polymers[48–50] and does not always apply to different polymer samples[51,52] even when run in the same column under the same conditions.[16] Calibration in FFF may also be performed using a set of polydisperse standards[53,54] or with a single broadly disperse sample when the relative molar mass is measured at two or more retention times by an absolute technique such as light scattering[55] or mass spectrometry.[56] It should be noted that absolute molecular weight (M) measurements made by FlFFF combined with mass spectrometry show an excellent data fit for $\log \lambda$ (and thus D) versus $\log M$ at molecular weight values far lower than those predicted from polymer theory.

2.5 Zone Broadening

The previous discussion on calibration in FFF assumed that broadening of the peak was due solely to molecular mass differences. In contrast, a number of concomitant effects contribute to the increase in peak width. A measure of zone spreading, and hence of resolution, is given by the plate height. As with other separative techniques, the overall plate height in FFF is given by the sum of contributing uncorrelated terms (Equation 28):

$$H = H_l + H_n + H_r + H_p + \sum H_i \tag{28}$$

In Equation (28), the zone spreading due to longitudinal diffusion H_l arises from concentration gradients along the sample plug and increases with the residence time. It is linearly related to the diffusion coefficient as $H_l = 2D/R\langle v \rangle$ and therefore becomes negligible for very slowly diffusing components such as macromolecules. In contrast, the nonequilibrium term H_n arising from the random displacement of component molecules across the channel is one of the dominant contributions to peak broadening in FFF. The band spreading associated with the time needed for the zone to reach the equilibrium position in the presence of the longitudinal flow, H_r, may be minimized by adopting a stop-flow procedure (see later). Other contributions, H_i, associated with system nonidealities such as dead volumes or injection volumes, may be disregarded in a well-designed channel. The spreading due to differences in a characteristic property such as molecular weight H_p is only an apparent broadening. It arises from the fact that individual molecules of a macromolecular or a particulate sample may differ somewhat from one another in their relative mass or size and are retained to a slightly different extent. If the difference in M is not large enough to produce distinct peaks, the sample zone will appear as a broadened peak with different mass elements continuously distributed in a molecular weight interval. It may be shown that (Equation 29):[57]

$$H_p = L S_M^2 (\mu - 1) \tag{29}$$

where $\mu = M_W/M_N$ is the sample polydispersity index which gives a measure of the departure of the weight-average molecular weight M_W from the number-average molecular weight M_N. For monodisperse samples, the two averages coincide. It appears from Equation (29) that the plate height, and hence resolution, strongly depend on the system selectivity S_M, which is defined as the retention volume difference of components of different M relative to the molecular weight difference (Equation 30):[58]

$$S_M = \frac{d \ln V_r}{d \ln M} = \frac{d \ln R}{d \ln M} \tag{30}$$

The subscript M denotes a molar mass-based selectivity whose value is a measure of the system ability to discriminate samples by their mass. Under conditions of high retention, the approximation $R = 6\lambda$ may be used and S_M becomes in the limiting form (Equation 31):

$$S_M = \frac{d \ln \lambda}{d \ln M} \tag{31}$$

Application of Equation (31) to Equations (21) and (24) shows that selectivity values for FlFFF and ThFFF coincide with the exponent of molecular weight, i.e. b in FlFFF and n in ThFFF. Assuming that the thermal diffusion is independent of molecular weight, b and n may be associated with the polymer molecule conformation in a given solvent and temperature system. From polymer theory, values of exponent b are predicted to be 0.33 for solid spheres, 0.5 for random-coil macromolecules[39] in Θ-conditions and about 0.7 for

flexible-chain polyelectrolytes.[59] The theoretical selectivity for FFF is considerably higher (0.5–0.7)[60] than that for SEC, where typical values range between 0.05 and 0.1.[58,61] Differences in selectivity when polymers are analyzed in organic solvents or aqueous solutions are expected considering that water generally behaves as a good solvent for hydrophilic polymers whereas Θ-systems are mostly reported for neutral polymers in organic solvents. The theoretical value of 0.588[38,62] for polystyrene (PS) in tetrahydrofuran is obtained in ThFFF at a specific cold wall temperature.[46] The same polymer, run in ethylbenzene by FlFFF,[63] gives a selectivity ranging between 0.51 and 0.56. Synthetic water-soluble polymers are generally fractionated with a selectivity above 0.6.[64–69] Polyvinylpyridine is an interesting example of a polymer that behaves as a neutral statistical chain in tetrahydrofuran and as a charged coil in water where it is soluble only as a polyelectrolyte. This polymer, bearing a six-term aromatic ring in the repeat unit, is fractionated with a selectivity of 0.51 in tetrahydrofuran by ThFFF and of 0.62 in an aqueous medium at low pH.[65] Systematic studies of polyelectrolytes in aqueous solution by FlFFF indicate a strong effect of the solution ionic strength on the selectivity, which generally decreases with increasing concentration of the added simple electrolyte.[68] Further investigations on the change in selectivity with the ionic strength of aqueous solutions and with the type of added electrolyte have been used to show specific interactions between the polymer and some metal ions.[69] Retention and selectivity in ThFFF of neutral polymers in organic solvents appear to increase with rising solubility parameters of the polymer–solvent system.[70] This effect was first registered in early investigations on ThFFF of polymers.[37] Comparative studies on the separation of copolymers by ThFFF and gel permeation chromatography (GPC) show that only the former yields a good separation of a diblock copolymer of poly(styrene-*co*-isoprene) from a triblock poly(styrene-*co*-isoprene-*co*-styrene).[71] This ThFFF separation is attributed to the difference in thermal diffusion coefficient of the two polymers.

2.6 General Theory of Asymmetric Flow Field-flow Fractionation

The general concepts of FFF were first developed for uniform field strengths and constant flow velocities along the channel. The symmetric FlFFF channel, shown in Figure 2(a), was designed to achieve these characteristics. In 1987, Wahlund and Giddings[72] introduced a new design of a FlFFF channel with only one permeable wall and no independent transverse flow. In this variant of FlFFF named "asymmetric FlFFF", shown in Figure 2(b), the permeable upper wall is replaced by a solid glass plate that conveniently allows visual inspection of the interior of the channel. Both the channel and crossflow originate at the channel inlet but exit the channel as two separate streams at the channel and crossflow outlets. Using this asymmetric channel configuration, a crossflow velocity gradient is established across the channel thickness. The sample concentration in the transverse coordinate in this design may no longer be described by Equation (3), but it approaches the exponential distribution of the standard FFF model for highly retained samples. Expressions for R and λ are found following the same mathematical procedure as in the symmetric configuration but taking into account that the flow velocity profile is linearly decreasing along the channel at a rate determined by the crossflow velocity. For high retention levels ($x/w \approx 0.1$), λ may again be approximated by Equation (9). Rectangular and trapezoidal[73] shaped channels have been used in asymmetric FlFFF. In the latter case, the breadth decreases as a function of channel length. An exponential

Figure 2 Different configurations of FlFFF channels. The symmetrical (a) and asymmetric (b) channels are commercially available and thus more commonly used than the hollow-fiber configuration shown in (c).

decrement in channel breadth[74] is shown to give a constant average channel flow velocity.

2.7 Retention in Hollow-fiber Channels

An interesting but commercially unavailable configuration of FlFFF utilizes a hollow cylindrical fiber with porous walls in place of the rectangular channel.[75] In this arrangement, illustrated in Figure 2(c), the axial flow is provided by an external pump connected with the inlet of the hollow-fiber membrane while the transverse flow is obtained by removing liquid radially from the channel with a second pump. The two flow velocity profiles in this configuration are different from any of the previously described FlFFF systems, both being variable with the distance Z from the inlet because of the pressure drop along the channel. From studies of fluid dynamics in hollow fibers,[76] it is found that the axial and radial flow velocities decrease exponentially as a function of Z and the permeability of the fiber and the fluid viscosity. Retention time in this type of channel is a function of channel length and Péclet number.

3 INSTRUMENTATION

An FFF system is generally assembled in a manner similar to that of a chromatographic apparatus. It uses most of the ancillary equipment employed in chromatography such as injector valves, pumps for the carrier liquid delivery, detectors, and some data acquisition devices such as chart recorders or more conveniently computers. A generalized FFF system is shown in Figure 3.

3.1 Flow Field-flow Fractionation

FlFFF is the most universally applicable FFF technique because any solute particle is subject to transport in a liquid stream. As shown in Figure 4, the spacer containing the channel form is clamped between two parallel blocks of some material such as Plexiglas, polyethylene, anodized aluminum, or stainless steel that accommodate two porous frit panels with 2–5-μm pores. Ceramic frits are more commonly used while polyethylene,[64,77] polypropylene,[18,78] and stainless steel[63,64,79] are generally employed with clamping blocks of the same material. An important component of the FlFFF channel is a permeable, generally polymeric, membrane placed over the accumulation wall to impede sample loss through the frit. Given the importance of the membrane in the successful application of FlFFF, a specific section (section 6.3) is dedicated to this topic. The design of the asymmetric FlFFF channel is somewhat different from that of the symmetric channel, as shown in Figure 2(b), but besides the dissimilarity of the channel geometry and the absence of the top porous wall it bears few differences from the symmetric FlFFF system. Some operational procedures, such as sample injection and relaxation, however, differ from those routinely used in the symmetric channel. A hollow-fiber channel has to be placed in a mantle, possibly of cylindrical symmetry, such as an empty stainless-steel chromatographic column, and the two coaxial tubes sealed to each other at the ends. The mantle must have a port connected to a crossflow pump that draws fluid out through the wall of the fiber. The channel flow is supplied by another pump connected to one of the hollow-fiber extremities. Sample injection and relaxation also in this case are particular to the set-up and will be dealt with in section 4.2.

Standard FFF theory assumes constant and uniform field strength and average flow velocity in the length and breadth dimension (edge effects not considered). Therefore, accurate control and continuous measurements of both these parameters are necessary when operating an FFF system. In FlFFF, the pump flow rates for both the longitudinal and transverse streams must be kept constant and continuously checked because, after mixing inside the channel, both flows may exit the channel through the outlet with the lower pressure. It is therefore of primary importance to equalize the pressures at the channel and crossflow outlets. This is achieved by placing back-pressure regulators at one or both outlets

Figure 3 FFF system assembled with the ancillary equipment.

and checking the pressure with in-line pressure gauges. An easy, cheap, but time-consuming method to check the flow rates is to measure the liquid volumes displaced over unit time with a buret and a stopwatch. Alternatively, a balance can be used to measure the weight of the carrier liquid exiting from each outlet as a function of time. The balance may be connected to a computer[80] to store data on time-dependent flow rates that may be used for accurate calculations of the retention parameters. This is particularly useful in programmed runs (see later) where the field strength, and hence the crossflow rate, is varied with some function of time.

3.2 Thermal Field-flow Fractionation

ThFFF channels (Figure 5) are formed by clamping a polyimide spacer (with the FFF channel volume removed) between two copper blocks with highly polished nickel or chromium surfaces. The field in this system is a thermal gradient that is provided by electrically heated metal elements inserted into one block and a stream of cold water flowing through the second block. Holes are drilled into the copper blocks to allow the insertion of temperature-measuring probes at different positions along the channel.

3.3 Detectors

Virtually any of the detectors used in chromatography is compatible with FFF apparatus. The HPLC separation

mechanism generally induces a concentration of the initial sample plug so that samples of continuously decreasing concentration may be detected. In FFF, the solute plug undergoes considerable concentration during the relaxation process[81] and considerable dilution during separation and elution. While reduction of the injected sample mass is always sought, particularly for high-molecular-weight polymer samples, the final concentration must be considered and the injected load adjusted to give a good signal-to-noise ratio. Nonspecific detection methods, such as refractive index[61,71,82,83] or viscosity,[84] may be generally used while others may be employed only when the solute is susceptible to specific response. This is the case for spectrophotometric detection, one of the most widely used methods in chromatography and FFF. Spectrophotometric detection

depends on the absorption of radiant energy of specific wavelengths by the chromophores. However, when the solute particle size becomes comparable to the detector wavelength, the output signal is considerably affected by light scattering. Consequently, the measured signal must be corrected in order to obtain an accurate mass distribution.[85] The Mie theory[86] used in these corrections takes into account the dependence of the scattered intensity on the particle size, the refractive index, and the scattering angles. Fluorescence detection is most often used with derivatized samples.[87] A recent development in polymer characterization is the coupling of FFF with a multiangle light scattering (MALS) detector.[88–91] This hyphenated system combines the high resolution capabilities of FFF with the absolute and independent molecular weight determination of light scattering, thus eliminating the need to calibrate the FFF system. The absolute determination of molar masses by MALS also allows for small nonidealities in the operating conditions such as fluctuations in temperature and flow rate. The best results are obviously obtained when optimum separation conditions are used and in the absence of nonidealities. The high fractionating capability of FFF is registered as an increase in the relative molar mass along the eluted peak as shown in Figure 6(a–c). The integrated FFF MALS apparatus has also allowed an in-depth study of the effect of experimental conditions such as injected sample mass or crossflow rate on the elution and fractionation of polymer samples.[92] A detailed discussion on these topics may be found in sections 6.1 and 6.2. The generally low sensitivity of laser light scattering detection is a problem, particularly for low-molecular-weight components and polyelectrolytes whose molar mass determinations are meaningful only at high ionic strength.[93] This problem has been overcome by coupling an electrospray mass spectrometer to a FlFFF channel[56] as mentioned in section 2.4.

4 EXPERIMENTAL PROCEDURES

4.1 Sample Preparation and Handling

No special treatment is generally required for the preparation of samples to be analyzed by FFF. Specific procedures, such as extraction, purification, and concentration, may be necessary for polymers of natural origin since synthetic polymers undergo sample purification as part of the production process. As mentioned previously, the narrow sample pulse injected in an FFF channel undergoes considerable changes in concentration as it is relaxed and fractionated[81] (see later). The concentration of the injected polymer sample solution is therefore a parameter that must be carefully controlled. Injection of large sample masses affect the plate height[94] even before the effect of overloading is registered by other retention parameters. The sample concentration during relaxation depends on the mass injected and can be one or more orders of magnitude higher than that of the initial sample solution depending on the retention ratio (concentration at the wall is approximately

equal to the sample concentration divided by λ which is expected to be ≤ 0.1). The effect of molecular dimensions on the concentration of polymer solutions is known from theory. Four model polymer solutions are generally identified: the dilute solution corresponding to a concentration of molecules separated by large volumes of solvent, the intermediate regime with a much reduced distance between polymer chains that may touch each other but still do not overlap, the semidilute, and the concentrated regime. In the last two cases, the polymer concentration is so high that chain entanglement dominates and the system may not be regarded as that of individual molecules suspended in a liquid medium. The solution properties are not governed by the properties of individual molecules and such systems will therefore have a behavior very different from that of any concentrated solution of small molecules. For this reason, the concentration c^* corresponding to that of the intermediate regime has been the subject of several theoretical and experimental investigations. In a number of studies, the dependence of c^* on molecular weight was found to follow a power law of the type $c^* \propto M^{-\alpha}$, where α is ~ 0.7.[95–97] From considerations of the polymer coil density and volume fraction Φ, it may be shown that the threshold value Φ^* for the transition between the dilute regime and the semidilute is related to the number of repeat units N in the macromolecular chain and the square of a characteristic parameter d/l (the ratio between the coil thickness d and its length l). An estimate of the volume fraction Φ^* shows that the onset of the semidilute regime occurs at much lower concentration for more elongated macromolecular chains. Theoretical findings are corroborated by experiments when the behavior of flexible chain polymers, for which the d/l value is between 1/2 and 1/3, is compared with that of DNA, which has a value of $\sim 1/50$. The critical concentration for this macromolecule hence decreases 2500-fold. The experimentally determined critical concentration reported for DNA is 2.2–2.6 μg per 100 μL.[98,99] An injection concentration 100 times lower than the critical value is recommended in FFF experiments. For synthetic polymers, concentrations of 0.05–0.50 g L^{-1} and injection volumes of 1–10 μL give easily detectable peaks under conditions of total sample recovery.[68]

4.2 Sample Injection and Relaxation

Sample solutions may be introduced into an FFF channel through an injection valve with a constant-volume loop such as those commonly used in chromatography or through an on-line tee-union fitted with a septum. The latter does not limit the injected volume but the polymer septum should be isolated from the channel with an on-line zero-dead-volume filter. When sample particles are first introduced into the channel, they are dispersed over the entire cross-section and experience the same field strength but different longitudinal migration velocities depending on their distance from the accumulation wall. While under the effect of the field alone the sample plug would concentrate in a narrow layer of exponential concentration. However, with displacement by the longitudinal flow, the plug undergoes a considerable dispersion along the channel length. This happens because molecules starting their migration far from the accumulation wall will take longer to reach the equilibrium position and will be swept ahead of species closer to the accumulation wall. A simple way to circumvent this problem and greatly reduce the relaxation contribution to the plate height is to halt the longitudinal flow as soon as the sample enters the channel. This stop-flow procedure allows the field to complete the sample relaxation process without the undesirable effects of differential migration velocities.[1] The stop-flow time, t_{sf}, depends on the channel thickness, the field strength, and the final transverse position of the zone's center-of-gravity. It has limits for low and high λ of $w^2/2D$ and $w^2/12D$, respectively. In practice, the relaxation process is started when all sample molecules have entered the channel. The delay time between the injection and the beginning of the relaxation is given by the ratio of the volume of the tubing between the injection port and the channel inlet and the volumetric flow rate. Although the stop-flow procedure has proven successful in yielding well-shaped peaks at the expected retention times, it is associated with a number of nonideal phenomena such as sample loss due to adsorption on the accumulation wall, baseline disturbance and increased analysis time. Different channel designs have been adopted to achieve sample relaxation without stopping the axial flow. A well-relaxed sample zone can rapidly form by applying a strong field in a small area localized at the channel inlet or by reducing the channel thickness in the same region. Hydrodynamic relaxation, currently applicable only to flow systems, may be achieved by isolating the inlet portion of the depletion wall and applying a higher field strength only in that area.[100] Sample components entering the channel are rapidly transported to the accumulation wall and relaxed. This system has been mostly used for biological macromolecules.[101] The pinched-inlet channel, applicable in principle to any FFF system,[102] has been tested experimentally on latex particles in an FFF channel under gravitational force.[103] Hydrodynamic relaxation obtained with a thin channel splitter[104] has been examined in SdFFF with latex particle samples.[105] Hybrid split and frit-inlet FlFFF systems have been designed and tested.[106]

The relaxation procedure in asymmetric FlFFF is somewhat different from that in a symmetrical system. It may be achieved virtually at any point along the channel

length by injecting sample material at a chosen distance from the channel inlet when two inflows of carrier liquid are introduced at both the channel inlet and outlet.[72] This procedure is termed ''opposing flows relaxation''. The two flows entering the channel through the inlet and the outlet meet at a focusing point that depends on the ratio between the inlet flow rate and the sum of the inlet and outlet flow rates. The focusing point in an asymmetric channel may thus be adjusted by selecting the flow rates. Alternatively, the flow entering through the inlet end may be eliminated so that only the reverse flow is maintained. This procedure defined ''reverse flow relaxation'' allows the sample to migrate to the very beginning of the channel and relax at the inlet point. When the opposing flows relaxation is used sample material may be loaded through either the inlet or the outlet or even an independent port at a given point along the channel. In this case, an additional pump must be used. The opposing flows approach has given rise to the opposed flow sample concentration procedure which allows very large volumes of dilute sample to be loaded on to a FlFFF channel.[107] As much as 10^5-fold concentration has been reported (1-L sample volume introduction). This sample concentration technique can be applied to symmetrical, asymmetric, and hollow-fiber FlFFF. In the hollow-fiber FlFFF technique, sample relaxation is obtained much as in the asymmetric set-up by pumping opposing flows in from the inlet and outlet while maintaining a constant radial flow.

4.3 Operation with Constant or Programmed Field

When complex mixtures have to be analyzed, differences in the property of interest of the species under investigation may be so large that no constant experimental condition may yield a satisfactory result for all species in a single run. This situation, well known in the chromatography of complex natural mixtures, is circumvented in HPLC with the so-called gradient elution, where the eluent composition is changed with time. The basic concept of gradually decreasing the retention power in order to let the most retained sample elute in a shorter time, thus gaining in detectability, has been applied to FFF.[108] Programmed field strength and/or flow rate are particularly useful for polydisperse samples whose elution would be spread over a wide time interval because of the high system selectivity. In FFF, there is an almost unlimited number of programming choices considering that both the field and the channel velocity may be varied as needed. In principle, the eluent composition may also be programmed but this option has only been applied to the carrier fluid density in SdFFF.[108] Both the fluid velocity and field strength may follow a step, linear, quadratic, parabolic, or exponential time-dependent function. In any of these forms of programming a period at constant conditions is usually applied to allow early-eluting particles to undergo adequate retention and separation before starting the programmed decrease of the field or increase of the fluid velocity. It has been shown that the fractionating power is a convenient universal parameter for comparing the effectiveness of different forms of programming. The diameter-based fractionating power, F_d, or the molecular-weight-based F_M, is defined as the resolution R_s of two sequentially eluting species divided by the relative difference in their size or molecular weight.[109] Linear and parabolic decay programs,[64,110] the first functions to be investigated for polymer separations, resulted in a considerable improvement over a constant field strength separation. However, closer examination showed an initial rise in F_d followed by a rapid decrease as the field strength went to zero.[111] The exponential field decay program introduced by Kirkland et al.[112,113] for particle size analysis by SdFFF has been applied to polymer separations by FlFFF[114] and ThFFF.[110,115–117] This type of program also resulted in an initial increase of the fractionating power followed by a strong decrease.[109] Only a power-law dependence of the field decay proposed by Williams and Giddings[118] yielded a constant molecular-based fractionating power for a wide range of molecular weights.[119]

5 APPLICATIONS

5.1 Organic-soluble Polymers

The high versatility of FFF has proven suitable to so many applications in different fields that a complete survey would be impossible. We therefore choose to report here only selected examples of the most innovative and recent applications. Many others may be found in the literature.

ThFFF with field-strength programming has been used to separate PS standards with molecular weights spanning 4000–7 100 000 Da. In Figure 7(a), the ΔT follows a parabolic function that decreases from 70 to 0 °C.[110] Since this early ThFFF work, the analysis time has been dramatically reduced to 20 min without significant loss of resolution by the advent of new instrumentation and the introduction of the power program function.[119] An application of this form of programmed elution is shown in Figure 7(b).

Although FFF was conceived as a separative technique, its rigorous theoretical background has demonstrated that measurements of fundamental physicochemical properties may be very accurate and in some cases unachievable by other techniques. This is the case for investigations of the thermal diffusion of polymers and copolymers and their correlation with the polymer and solvent chemical composition. Studies in this field showed a linear relationship between the thermal diffusion coefficient D_T and the

temperature at the center of the sample zone for PS in ethylbenzene[36] and a similar correlation between D_T and the mole fraction of one of the monomers in random copolymers.[120] This finding has a number of implications, one of which is that ThFFF has an additional separating dimension that allows samples to be resolved according to chemical composition as well as hydrodynamic size. This is shown in Figure 8, where the diblock copolymer poly(styrene-*co*-isoprene) is separated from the triblock of same size poly(styrene-*co*-isoprene-*co*-styrene) only by ThFFF. Hydrodynamic chromatography (HDC), another analytical technique for polymer separations, has a higher efficiency than FFF but, like GPC, discriminates samples only by size. Consequently, fractions of PS, polyisoprene and polybutadiene (PB) with similar hydrodynamic dimensions are only partially separated by HDC whereas they are completely resolved by ThFFF[121] because of their different thermal diffusion coefficients. Although retention in ThFFF is dependent on D_T, the evaluation of absolute values of this parameter is not straightforward since the measurable retention parameter λ yields values of D/D_T. D_T alone may therefore be determined only if the diffusion coefficient is measured by an independent technique. One approach is to couple SEC to ThFFF and determine D using light scattering. This multidimensional approach allows the fractionation of polymer samples according to size by SEC and to thermal diffusion by ThFFF.[122,123] The usefulness of the combined SEC/ThFFF technique is demonstrated in the analysis of polydisperse samples of copolymers whose relative composition, which may vary with molecular weight, gives rise to materials with different properties. The preliminary fractionation of a polydisperse sample of PS by SEC may occur with a selectivity of 0.15 in the molecular weight range 150 000–1 000 000 Da and drops to 0.04 for lower M fractions.[122] This selectivity, well below that commonly found in FFF, is obtained after a system calibration with well-characterized PS fractions and the light-scattering determination of diffusion coefficients. The thermal diffusion coefficient, calculated from retention measurements once both molecular weight and ordinary diffusion coefficients are known, is generally independent of molecular weight.[124] Fractionation according to

Figure 9 (a) Size exclusion chromatogram of a blend of PS, PB and PTHF and (b) ThFFF of individual fractions taken after the SEC elution. Numbers along the *y*-axis of the ThFFF fractogram correspond to the labeled SEC fractions in (a). (Reprinted from A.C. van Asten, R.J. van Dam, W.Th. Kok, R. Tijssen, H. Poppe, *J. Chromatogr. A*, **703**, 245–263 (1995). Copyright 1995, with permission from Elsevier Science.)

differences in thermal diffusion coefficient alone gives information on the copolymers' chemical composition. Figure 9(a) and (b) show the partial fractionation (a) by SEC of a blend of PS, PB, and polytetrahydrofuran (PTHF) and then (b) by ThFFF of some SEC fractions collected at different retention times. The ThFFF fractogram indicates the presence of different polymer species (fractions 3–6) whose measured D_T are in good agreement with values of the corresponding PB and PTHF homopolymers determined by ThFFF and light scattering, e.g. 0.22×10^{-7} and 0.47×10^{-7} cm^2 s^{-1} K^{-1} versus 0.23×10^{-7} and 0.50×10^{-7} cm^2 s^{-1} K^{-1}.[125]

The measurement of the thermal diffusion coefficient has become a key step in the determination of copolymer relative chemical composition. Two styrene–methyl methacrylate copolymers with different styrene content analyzed by SEC/ThFFF[122] show different D_T versus retention time trends when analyzed by ThFFF, although the SEC traces are almost identical. Using a calibration plot for the SEC column based on PS standards (which is not a rigorous procedure), the fractions may be assigned a molecular weight and D_T may be related to this parameter. The invariant trend of the thermal diffusion coefficient of one sample and the clearly increasing values of the second sample suggest that the styrene percentage is different and that it increases with M in the second case.[122] Increasing D_T with increasing weight fractions of vinyl acetate is reported for poly(ethylene-*co*-vinyl acetate) copolymers.[83] Multidimensional analysis may also be obtained by coupling a ThFFF system with HDC.[126] Samples with the same D/D_T eluting from the ThFFF system are subsequently fractionated according to size by HDC.

ThFFF appears to be the only separation technique suitable for the analysis of gels and rubbers[82,90,127] because irreversible adsorption evident in other methods is minimized.[90,127] In addition, the need to filter samples prior to their injection into a GPC column results in the removal of high-molecular-weight polymer components as well as of the gel. This causes the average molecular weight and molecular weight distributions to be consistently lower in GPC than in ThFFF.[127] The open FFF channel design eliminates the problem of plugging that is encountered in GPC when gel containing samples are not filtered before the analysis. Hence polymer and gels may be completely separated within a single run by ThFFF,[128] as shown in Figure 10.

Polym. Sci.*, **60**, 1695–1707 (1996). Copyright © 1996, John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Molecular weight and particle size distributions are calculated for both the polymer and the gel components. Although other techniques have been used successfully to analyze gels and rubbers, SEC has been considered the separative methodology par excellence in spite of its limitations.[129,130] It was shown that the different D_T values for different polymers have been exploited in the ThFFF analysis of core-shell latex particles.[131] The retention time is sensitive to the composition of the polymer shell. A calibration curve may be drawn to relate retention time and percentage of methacrylic acid in the shell. The sensitivity of D_T to the particle surface composition is further illustrated using similar sized particles of different polymeric and inorganic surfaces.[132,133]

5.2 Water-soluble Polymers

Early studies in ThFFF[37] showed that different organic solvents had a very similar effect on the retention of polymers. In contrast, when water is used as the carrier liquid, the thermal diffusion factor α is very low and retention is negligible unless a considerable amount of some organic solvent (~60%) is present. Except for a few results confirming the poor retention in such a solvent,[117] water-soluble synthetic polymers have been analyzed by the most versatile technique of the FFF category, FlFFF. This technique was recognized since its first appearance as highly suited to polymer fractionation.[134,135] Although resolution and analysis time were not optimized, the early results allowed the determination of molecular parameters, such as hydrodynamic size, on the basis of theoretical concepts that have subsequently been extensively confirmed. Polyacrylamide (PAAm) is a widely employed polymer in many fields that is difficult to characterize and fractionate. Commercially available fractions of PAAm generally have a broad distribution.[136] The FlFFF fractograms of the three PAAm samples illustrated in Figure 11 consistently show the presence of low-molecular-weight components in each polymer sample.[68] A similar peak asymmetry is also observed for broadly disperse samples in organic solvents.[63] As mentioned earlier (section 2.4), in the absence of an absolute technique for the molar mass determination, the molecular weight distribution may be accurately determined by calibration. The calibration procedure, however, should be performed with narrowly distributed, well-characterized standards of closest possible chemical composition to the unknown. When standards with these characteristics are not available, absolute measurements of the diffusion coefficient may be used to evaluate the polymer hydrodynamic size using the Stokes–Einstein equation. The absence of non-ideal sample–wall interactions on the elution of PAAm is verified by comparing measurements

Figure 11 FlFFF separation of three samples of PAAm of different nominal molecular weight. The hydrodynamic diameters were determined using two different membranes. (Reproduced from M.-A. Benincasa, J.C. Giddings, *J. Microcol. Sep.*, **9**, 479–495 (1997). Copyright 1997, John Wiley & Sons, Inc. Reprinted with permission of John Wiley & Sons, Inc.)

made in solutions of identical ionic strength but with membranes of different composition, namely poly(ether sulfone) and cellulose.[137]

As discussed in the theory section, the overall polymer molecular dimensions are anticipated to depend, to a certain extent, on the properties of the surrounding medium. This effect is expected to be enhanced for charged polymers. The effect of solvent and ionic strength was identified in the first study in FlFFF of water-soluble polymers.[135] Poly(ethylene oxide) (PEO), a polymer widely used in biomedical and biotechnological applications because of its non-toxicity, shows an almost ideal correlation between the measured diffusion coefficient and molecular weight in aqueous sodium sulfate solutions.[69] Similar to the observation reported by Hassellöv et al.,[56] this correlation is found for polymers with molecular weights well below the range for which the general polymer scaling laws are expected to hold. The correlation between diffusion coefficient and molecular weight in potassium sulfate is very different to that in sodium sulfate. The authors attribute this difference to the capability of low-molecular-weight PEO fractions to form complexes with some metal cations, as reported in independent studies.[138] The elution profiles of PEO samples in a molecular weight range 250 000–1 000 000 Da may be obtained by FlFFF with good resolution as shown in Figure 12. Charged amphiphilic graft copolymers are a particular type of sample that may dramatically change their conformation in different solvents because of the presence of hydrophilic and hydrophobic

Figure 12 Separation of three PEO samples by FlFFF in aqueous 0.025 M Na_2SO_4.

moieties derived from different homopolymers. In aqueous solutions, they form a hydrophobic core with the hydrophilic moieties on the surface. At low pH and in the presence of salts, aggregation may occur for the copolymer of styrene, methyl methacrylate and maleic anhydride with grafts of poly(ethylene oxide) monomethyl ether (MPEO).[139] The polymer molecular conformation and solubility in water depend on the pH, which affects dissociation of the carboxyl groups, and on the solvent ionic strength. An extended conformation may exist at high pH or aggregation may occur at low pH and high ionic strength. The copolymer hydrodynamic diameter increases with decreasing pH. This effect is attributed to the formation of aggregates of less charged copolymers at low pH, a phenomenon that seemed amplified when long stop-flow times are used. When a ca. 0.002 M buffer solution is used as the carrier liquid, the molecular dimensions are considerably higher (16–40 instead of 2–20 nm) than those measured in unbuffered solutions. It is postulated that the buffer salts cause shielding of charged sites which consequently promote aggregation through hydrophobic interactions of the polymer backbone. Formation of aggregates is evidenced by the particle size distributions shown in Figure 13.[140]

SdFFF is a technique usually associated with particle rather than polymer analysis. The maximum field strength or centrifuge speed of currently available commercial instruments is insufficient to induce transport of the polymers to their equilibrium positions at the accumulation wall. Consequently, retention and separation by SdFFF are poor. However, an instrument with high-field-strength capabilities can be used to characterize high-molecular-weight polymers.[141]

Figure 13 FlFFF-derived particle size distributions of an amphiphilic grafted copolymer poly(styrene-*co*-methyl methacrylate-*co*-maleic anhydride) and MPEO. Aggregation is observed as the sodium sulfate concentration is increased. The carrier liquids used were (A) pure water, (B) 1 μM Na_2SO_4, (C) 10 μM Na_2SO_4, and (D) 100 μM Na_2SO_4. 6 METHOD DEVELOPMENT

6.1 Determining Experimental Conditions

Before starting an analysis, specific requirements may be set for a number of experimental parameters such as analysis time, resolution, and selectivity. A thorough discussion of this topic would require a long navigation through FFF theory and is beyond the scope of this article. Therefore, some practical recommendations are given here with reference to theoretical fundamentals on which they are based. Demonstration of these concepts may be found in the specific literature and will not be dealt with here. A generally desired characteristic is short analysis times. The retention time in FFF is linearly related to the applied field strength, ceteris paribus. This translates into a dependence on the temperature gradient, crossflow rate, solvent viscosity, channel thickness, and void volume.

Although in theory values of these parameters may be accurately determined, common laboratory practice has shown that void volume V^0 and channel thickness determination in FlFFF is not a trivial procedure. A peak breakthrough technique[142] has been proposed that allows the determination of the channel void time, and related volume, from the time needed for an unretained sample to emerge from the channel under high-flow-rate conditions. Experiments must be carried out with great care and in the total absence of a crossflow. A simple way to ensure this is to block the crossflow inlet and outlet. More accurate void volume determinations may be obtained by sandwiching the spacer and the membrane between two glass plates with holes drilled through one of the plates to act as the channel inlet and outlet. The determination of the actual void volume in FlFFF may not be bypassed since it also yields a measure of the channel thickness. This last parameter is the most critical in FlFFF since the retention time varies with w^2. Molecular weight measurements, obtained from retention parameters, are strongly affected by the channel thickness. The crossflow rate $\dot{V}_c$ and channel flow rate $\dot{V}$ have opposing effects on t_r since they contribute as the ratio $\dot{V}_c/\dot{V}$. An increase in the two flow rates which does not alter this ratio would have no effect on t_r. However, λ and t^0 would decrease. This would translate into a decrease of the retention ratio t^0/t_r and a higher compression of the sample zone with a greater probability of overloading and sample interaction with the accumulation wall. Resolution, which depends on $(\dot{V}_c^3/\dot{V})^{1/2}$, would increase with the 3/2 power of the crossflow rate and decrease with the 1/2 power of the channel flow rate. Studies on the effect of field strength and injected sample load on polymer fractionation by FlFFF have shown that the molar mass distribution seems to broaden with increasing crossflow rates or decreasing injected sample loads.[92] Unlike ThFFF, where the flow profile is considerably affected by the field, perturbations due to the crossflow in FlFFF are negligible.[143] In general, axial flow rates of 0.2–2 mL min^{-1} are used for polymer analysis. Low flow rates and velocities protect samples from shear degradation and peak broadening due to the nonequilibrium contribution to the plate height that depends linearly on the flow velocity.

Unlike FlFFF, the retention time in ThFFF does not depend directly on the channel thickness. It depends on the void time t^0, which is related to w. The retention time is a function of the thermal gradient dT/dx, which can be increased by reducing w or increasing the hot wall temperature. The first approach is useful when the working temperature is above the solvent boiling point and further pressurization of the system to elevate the boiling point[3] is not an option. However, the reduction of w in ThFFF is limited by heat transfer that may require substantial heat fluxes between the hot and cold walls. In addition to the previous considerations, w affects resolution and sample dilution in all the FFF techniques. Generally, 90–99% of the FFF channel volume is occupied by pure solvent during elution. The injected sample is hence very diluted on elution from the FFF channel. This effect may be reduced using stream splitters[104] or frit outlet systems.[100] All channel dimensions may in principle be varied. An increase or reduction of either b or L has some advantages and some disadvantages. An extensive discussion on the theoretical and practical aspects of changing these dimensions is reported in the literature.[144] The dimensions of asymmetric FlFFF channels are subject to more constraints.[145] Commonly used channel flow rates in ThFFF are of the same order of magnitude as those used in FlFFF. Data collected over a 15-year period using a number of different channels have shown that retention in ThFFF is affected by the absolute value of the cold wall temperature T_c.[146] Higher T_c values lead to lower retention with the same ΔT. The use of binary solvents in ThFFF has been shown to enhance retention considerably in some cases. This result may be used to extend the range of applicability of ThFFF toward lower molecular weight limits.[147]

6.2 Effect of Sample Size

Sample size effects on retention were described in early FFF studies.[135] These effects, common to other separation techniques, manifest themselves in FFF as distortions of the elution profile and shifts in retention time that cannot be related to any sample physicochemical property but rather to the amount of sample injected. It was also recognized in the early FFF work that the ionic strength changes remarkably the effect of sample load on retention time.[135,148] The effect of sample load depends on the polymer–solvent system rather than on the FFF technique employed. The general trend of increasing retention time with increasing injection amount is observed for FlFFF and ThFFF of PS in ethylbenzene and tetrahydrofuran.[81,149] In this case the role of molecular weight in enhancing the effect of load even at very low ΔT values was shown. Longer retention times are also reported for higher amounts of PTHF analyzed in toluene by ThFFF.[150] The opposite trend is found in aqueous separations of particles by SdFFF[148] and for synthetic[65,68,135] and biological polymers.[151] The dependence of sample overloading on the physicochemical properties of the polymer–solvent system rather than on the analytical technique is substantiated by the findings that aqueous synthetic and biological polymer systems also show a decrease in retention time with increase of load in
